Normal Developers. In the normal fine grain developer, the energy is reduced by lowering the alkalinity. The classic developer of this type is the metol-hydroquinone-borax formula (Kodak D-76, Defender 6D and Ilford ID-11):

Metol	35 grains	2 grams
Sodium sulphite, anhyd.	4 ounces	100 grams
Hydroquinone	88 grains	5 grams
Borax	34 grains	2 grams
Water to make	40 ounces	1,000 c.cm.

Average development times are about 10–20 minutes at 65° F. (18·4° C.).

There are three types of variation on this formula:

(1) The concentration of the developing agents may be varied. Some M.Q.-borax formulae contain less hydroquinone; others contain no hydroquinone at all, but have extra metol; others contain another developing agent such as glycin in place of the hydroquinone. The metol can also be replaced by 1/15 to 1/10 its weight of phenidone.

(2) The alkalinity may be increased by using an equal amount of metaborate or Kodalk instead of the borax, or by using more borax.

An increase in the borax or metaborate concentration will, other things being equal, slightly increase the grain and decrease the development times. This effect is particularly marked with Kodalk where a 2½ times increase in the alkali concentration cuts the development time by half.

(3) The alkalinity may be further stabilized, or even decreased by using a buffer mixture of borax and boric acid.

Thus the stabilized version of M.Q. borax contains 8 grams each of borax and boric

The quantities are in grams per 1,000 c.cm. of solution, or parts per 1,000.

acid instead of 2 grams of borax alone. The grain and development time remain unchanged.

A somewhat different type of low alkalinity fine grain developer uses only metol and sodium sulphite. It is simply a 0·75–1·5 per cent solution of metol in 10 per cent sodium sulphite. The sulphite acts as alkali as well as preservative. The addition of 1–2 per cent of sodium bisulphite reduces the alkalinity still further and gives a buffered developer. Either of these formulae act as surface developers, building up the image first in the top of the emulsion layer before going deeper. This helps to increase the image resolution, quite apart from any improvement in grain. Over-development will, however, nullify this advantage.

Low Energy Developers. Developers of this type aim at reducing grain by using low energy developing agents in weakly alkaline solutions. (Para- and ortho-phenylene diamine are suitable developing agents, often used together with one or two normal agents.) The low activity of the developer decreases the effective film speed, and exposure may have to be increased as much as three times. The image contrast is usually low because the developers are incapable of producing high contrast and development is usually shortened to keep contrast low and grain subdued.

The basic superfine grain developer of this type is a 1 per cent solution of para-phenylene diamine in 9 per cent sodium sulphite. This is the Sease I formula. It gives very fine grain, but its activity is so low that the development time may be 45 minutes or more. In addition the effective film speed is reduced so seriously (up to 300 per cent extra exposure may be needed) that it is more sensible to use a slow fine grain film and develop in a normal fine grain developer. For this reason the formula is nearly always modified in one or more ways:

(1) A second developing agent may be added. In the Sease series this is glycin; Edwal 12 contains 0·6 per cent metol in addition. The Johnson fine grain developers use pyrocatechin as the second developing agent.

(2) An alkali may be added either to the plain para-phenylene diamine formula, or to its combination with a second developing agent. The alkali needs a fairly strong buffering activity. Trisodium phosphate is often used, and so is borax. The alkali concentration may be comparatively high.

Solvent Developers. In developers of this type, the fine grain is the result of adding a solvent of silver halide. This dissolves away part of the silver bromide grains during development, and in this way physically reduces clumping. At the same time some of this dissolved silver salt is developed and deposited as silver on the film, mainly on those parts of the emulsion which already carry a silver image. This is really a chemical process but it is known as physical development to distinguish it from the normal direct development of the silver salts to silver.

The common solvents are potassium thiocyanate, ammonium chloride and sodium thiosulphate (hypo).

Most of the action of a solvent fine grain developer is normal direct development, with some indirect physical development. But some developers rely almost entirely on depositing silver from the solution. In fact, they actually contain silver salts before development. These are the real physical developers.

The solvent type of fine grain developer removes silver from the emulsion so some of the latent image goes with it. This is another reason why the negative material needs extra exposure of anything from 50–100 per cent according to the type of emulsion.

Both solvent and low energy developers are classed as super fine grain developers.

Nearly all fine grain developers use a high concentration of sodium sulphite (8–10 per cent, as compared with an upper limit of 3 per cent for most normal negative developers). So fine grain developers keep well in solution, and can be used repeatedly. The high concentration of sulphite also helps by acting as a weak solvent.

One advantage of the solvent fine grain developers is that they give as fine grain as the low energy developing agents, but produce the same negative density and contrast quicker.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The formulae are mostly derived from the normal M.Q. borax and similar fine grain developers, with the addition of 0·1–0·3 per cent potassium thiocyanate or sodium thiosulphate. Most solvent fine grain developers call for slightly increased exposure.

Modern Fine-grain Developers. Both low-energy and solvent fine-grain developers are nowadays comparatively obsolete since the same combination of effective speed and fine-grain can be obtained by using a slower fine-grain film and developing this in a higher-energy developer.

A number of current proprietary fine-grain developers concentrate more on the use of mixtures of low and high energy developing agents in a moderately alkaline solution (achieved, for example, by the use of borax or metaborate). Such formulae fully utilize the emulsion speed of the film, yet yield reasonably fine-grain by avoiding the clumping of silver grains encountered with highly active M.Q. formulae.

A second advantage of a number of formulae of this kind is that they are concentrated solutions which can be diluted ten or more times for use. One lot of developer then serves for just one film and can be discarded afterwards.

High-definition Developers. With modern thin-emulsion films neither solvent nor low-energy developers yield the best results. The image there is easily attacked by the silver halide solvent action with adverse effects on negative quality. Moreover, such films of themselves yield appreciably finer grain than the average negative materials available at the time when special fine grain developers were highly popular.

With thin-emulsion films there is a greater risk of loss of image detail through lack of sharpness (due to image diffusion) rather than through graininess. Also such films tend to be contrasty and therefore require a soft working developer.

This has led to the emergence of high-definition developers which yield a soft gradation image that is concentrated in the surface of the emulsion rather than in depth. Developers of this kind are usually based on metol in an alkaline solution, or on para-aminophenol. Being surface developers, they yield maximum image sharpness, utilize the film speed to the greatest extent, and do not adversely affect the grain (which is fine anyway).

A typical formula, worked out by W. Beutler for slow films, is:—

Stock Solution A.		
Metol	175 grains	10 grams
Calgon	35 grains	2 grams
Sodium sulphite, anhyd.	2 ounces	50 grams
Water to make	40 ounces	1,000 c.cm.
Stock Solution B		
Calgon	35 grains	2 grams
Sodium carbonate, anhyd.	2 ounces	50 grams
Water to make	40 ounces	1,000 c.cm.

One part of each stock solution is mixed with ten parts of water.

A number of proprietary high-definition and fine-grain developers are based on similar principles. The developer may be made more active to yield higher contrast with medium speed (and hence less contrasty) films.

MONOBATH DEVELOPERS

Normally the developing and fixing processes are kept strictly separate. Under certain conditions the fixing chemicals can however be incorporated in the developer, so that both actions take place simultaneously. Monobath developers working on this principle have been known for a considerable time, but have only in recent years gained some practical importance. The earlier combinations of developer and fixer usually involved considerable loss of emulsion speed, fog and uneven action.

A number of photographic firms now market monobath developers that yield acceptable to good results.

A typical formula is:—

Hydroquinone	265 grains	15 grams
Sodium sulphite, anhyd.	2 ounces	50 grams
Phenidone	175 grains	10 grams
Potassium alum	320 grains	18 grams
Sodium hydroxide	320 grains	18 grams
Sodium thiosulphate, cryst.	2½ ounces	60 grams
Water to make	40 ounces	1,000 c.cm.

Since monobath development goes to completion, neither development time nor development temperature are particularly critical. As fixing proceeds together with development, the process is usually completed in 4 to 6 minutes; at higher temperatures both actions proceed faster and in colder solutions both take longer. There is thus no possibility of over-development.

On the other hand the balance between developing and fixing activity is fairly critical. A given monobath developer is thus suitable for only a limited range of negative materials, and different monobath formulae are usually necessary to deal with slow developing and fast developing emulsions. Some manufacturers have produced monobath developers in the form of two stock solutions, using them in different proportions for different films.

In practice, monobath development has appreciable advantages, especially in hot weather since the film spends only a short time in the processing baths. Also the use of a single solution—usually in concentrated form—is particularly practical for processing while travelling.

Against this high degree of convenience is the fact that monobath developers yield neither a very fine grain nor a very high degree of image sharpness in comparison with high-definition developers.

POSITIVE DEVELOPERS

The range of developing agents suitable for bromide and contact papers and lantern plates is limited. Developers with a tendency to stain

(e.g., pyro) cannot be used because the image colour of a print is important. The only agents of any importance for black tone development are metol, hydroquinone, amidol, and occasionally para-aminophenol. The agents used in warm tone developers (which can only be used with special chlorobromide papers and warm tone lantern slides) are chlorquinol, glycin, and sometimes pyro (with slides).

Positive prints do not call for low energy or fine grain developers; the grain size of a printing paper is of no importance—the image will not be enlarged, anyway. Even lantern slides have a grain that is very much finer than that of the negative.

The most popular formula is metol-hydroquinone with carbonate, and with glycin and (or) chlorquinol added for warm tone formulae. The only exceptions are certain special formulae for lantern plates or for high contrast, such as caustic hydroquinone, pyro, and certain warm tone developers containing ammonia or thiocarbamide for lantern slides. Very occasionally a physical developer is used for slides.

Characteristics. Positive developers can be classified as:

(1) Standard black tone bromide and contact paper developers. These also give black tones on bromide and contact lantern plates, and warm black tones on warm tone materials.

(2) High contrast and variable contrast developers for bromide papers and black tone (bromide) lantern plates. Contact (chloride) papers and plates do not respond so well to high contrast and variable contrast development. With warm tone (chlorobromide) papers and plates the contrast obtained is to some extent decided by the image colour aimed at.

(3) Warm tone developers. These are used almost exclusively with warm tone (chlorobromide) papers and lantern plates. Special warm tone developers for bromide papers have been published, but their action depends very greatly on the make and grade of the paper. Usually such warm tone bromide developers work with one or two makes only, and are not suitable for all black tone papers and plates. In any case the degree of control over the image colour is limited, and the tones are often distinctly unpleasant.

Positive M.Q. Developers. These developers are all based on the standard negative M.Q. formula.

Generally speaking, the main difference between negative and positive developers of this type is that while negative developers are mostly used fairly dilute (particularly for tank development), developers for bromide papers and black tone lantern plates are used in a much more concentrated solution. The developer for contact papers and chloride plates is used stronger still.

It is therefore possible to use one and the same formula for negatives, lantern slides, bromide and contact papers, by merely diluting the stock solution to suit. This is the basis of most of the so-called universal developers, like Focal Universal, Kodak D-163. The reason is simply that a standard M.Q. developer will develop almost any sensitive material.

There are several recognized departures from the standard formula.

First, papers have a tougher emulsion than negatives; it is less apt to swell or melt. So paper developers can be more alkaline and often contain up to 2 per cent sodium carbonate (or up to 4 per cent in the double strength contact paper developer).

Second, for really black tones, the potassium bromide concentration must be kept down to a minimum. This minimum amount of bromide needed to avoid fog varies from paper to paper, and also depends on the activity of the developer. That is partly the reason for the large number of formulae each specially recommended by a maker for his particular paper or papers.

Generally in bromide paper developers the potassium bromide content is near the lower limit of the range stated in the standard negatives M.Q. formula (about 0·07–0·1 per cent, or even less).

In some developers, particularly those designed for contact papers, the bromide concentration of the working solution is still less (0·04–0·06 per cent) even at the contact paper

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

strength of the solution, i.e. when the concentration of all the other ingredients is twice as great as in the standard M.Q. formula. When the developers are diluted to normal strength for bromide papers or lantern plates, the amount of potassium bromide is only half as much.

With positive developers the use of a developer improver helps to give good black tones with the minimum of fog. The developer improvers are added in the proportion of about 1 part of the commercial solution to 100 parts of working developer. Some developers actually include a developer improver.

One typical formula is:

Metol	60 grains	3·5 grams
Sodium sulphite, anhyd.	1½ ounces	35 grams
Hydroquinone	150 grains	8·6 grams
Sodium carbonate, anhyd.	2½ ounces	63 grams
Potassium bromide	33 grains	1·9 grams
Developer improver	1½ ounces	37 c.cm.
Wettol	190 minims	10 c.cm.
Water to make	40 ounces	1,000 c.cm.

The developer improver may be any one of a number of proprietary solutions on the market, or a solution containing 1 per cent benztriazole and 1 per cent sodium carbonate.

For use dilute 1 part with 2 parts water.

Positive Amidol Developers. Amidol was at one time very popular for bromide and contact papers, mainly because it very easily gives pure black image tones. But a standard M.Q. developer will give as good blacks if the potassium bromide concentration is kept low, or a developer improver is added. The disadvantages of amidol developers are that they do not keep well and must therefore be made up immediately before use, and that they stain the fingers.

AMIDOL DEVELOPERS

	Ansco 113	*Defender 61D**	*Ilford ID-22**	*Kodak D-170**	*Ilford ID-30†*	*Kodak D-162†*

Water to make	1,000	1,000	1,000	1,000	1,000	1,000

*Mainly bromide paper developers.
†Mainly chloride paper developers.
Quantities are in grams per 1,000 c.cm., or parts per 1,000.

The developer itself is simply amidol, sodium sulphite, and potassium bromide. No alkali is needed; the low alkalinity of the sodium sulphite solution is quite sufficient.

High and Low Contrast Developers. The contrast obtainable with any one grade of bromide and contact papers or lantern plates can be slightly modified by using a high or low contrast developer.

The high contrast developers are much the same as the standard caustic hydroquinone or hydroquinone and carbonate developers used for negatives but the bromide content can be lower. Apart from their increased contrast, they differ from the normal M.Q. developers in three ways:

(1) The image colour is not a pure black, but slightly warm black because of the high bromide content of the hydroquinone developer. Even on standing, the working solution deteriorates rapidly and gives an unpleasant greenish black image. As the developer becomes exhausted, the effective speed of the paper decreases and the print needs a longer exposure.

(2) The solution very readily stains the paper base yellow-brown. This again is more marked as the developer deteriorates so forcing development beyond 2 minutes at 65° F. (18·4° C.) does more harm than good.

(3) The effective exposure latitude of the paper or lantern plate is increased. The positive can therefore be over-exposed by as much as 50 per cent (and development time reduced accordingly) without any falling off in print quality.

Low contrast is given by negative developers of the metol group. Again the potassium bromide content should be kept to a minimum. These developers keep well and do not stain but the printing exposure is critical; print quality deteriorates if the exposure is varied by more than about 10 per cent.

The contrast difference between caustic hydroquinone and standard M.Q. is equivalent to about half a paper grade.

Combinations of hydroquinone, M.Q., and metol formulae are used as variable contrast developers either separately in multi-dish methods of development, or mixed in varying proportions.

Warm Tone Developers. Most warm tone developers are suitable both for warm tone lantern plates and chlorobromide papers. They differ from normal black tone paper and slide developers in the following respects:

Developing agents: as metol tends to produce blue-black tones, it is used only in small amounts in warm tone developers; in many formulae it is left out altogether. But the amount of hydroquinone is fairly high, and is often supplemented by chlorquinol and glycin, both of which readily give warm image tones.

Preservative: the amount of sodium sulphite is more or less the same as in normal positive developers, although some hydroquinone formulae contain rather more sulphite to increase their keeping qualities. When they are made up in concentrated stock solutions (with the alkali separate) the hydroquinone stock solution many contain either potassium metabisulphite or citric acid to prevent premature oxidation.

Alkali: the proportion of alkali is the same as for normal M.Q. developers, but the actual concentration varies a great deal, since many

The quantities are in grams per 1,000 c.cm. or parts per 1,000.
F.S. = full strength. The dilution figure signifies the number of volumes to which the solution is diluted; e.g., 2x = diluted 1 : 1 to make 2 volumes.
Image colours: W = warm black, B = brown, WB = warm brown, BB = brown black, S = sepia, RB = red brown, R = red.

formulae may be diluted up to 10 or 20 times for the warmest tones.

Some warm tone developers even use ammonia in addition to sodium carbonate. This gives purplish brown tones. Many of the image colours obtained in this way are generally more suitable for lantern slides.

Restrainer: with most warm tone developers it is principally the potassium bromide that controls the image colour. The actual concentration of potassium bromide included varies from formula to formula. It may be as low as 0·03 per cent, or as high as 0·3 per cent (0·3–3 grams per litre).

The more potassium bromide there is in the developer, the warmer the tone. For this reason extra potassium bromide (as 10 per cent solution) is often added to the diluted developer. With certain formulae the bromide concentration of the working solution is kept more or less constant in this way, irrespective of the concentration of the other ingredients.

Potassium bromide lowers the effective speed of the chlorobromide paper or warm tone slide so for warmer tones much longer exposures are therefore needed with developers containing a lot of potassium bromide. The desired effect with any particular developer and make of paper can only be arrived at by experiment. The whole range of tones is, however, warmer with the more heavily restrained developers.

Special Warm Tone Developers. While practically all the standard warm tone developers will work equally well with both papers and lantern plates of the warm tone type, there are a few formulae mainly suitable for slides only.

Ammonia (purplish) tones are produced by adding ammonia or ammonium bromide and ammonium carbonate to the developer. The colour appears to its best advantage when projected or viewed by transmitted light.

The basic developer for this range of tones is a standard bromide paper developer with varying amounts of a 10 per cent solution of ammonium bromide and carbonate added as restrainer (1–10 parts restrainer to 20 parts developer).

Thiocarbamide tones, which range from grey to violet, can be obtained with the above developer by adding 1 part in 20 of a solution of 0·8 per cent thiocarbamide and 0·3 per cent ammonium bromide. A warm tone developer—preferably glycin or glycin-chlorquinol—used instead of the standard M.Q. and ammonium bromide/carbonate mixture is even better.

DILUTION OF DEVELOPERS

For reasons of convenience many modern developers are made up or sold in concentrated stock solutions requiring dilution before use. The degree of dilution depends on the initial concentration of the stock solution (which is limited by the solubility of the ingredients) and the purpose for which the developer is used. Thus the solution is generally diluted more for tank than dish development of negative materials or for development of papers.

The degree of dilution affects:

(1) The development time.
(2) The contrast.
(3) The exhaustion.
(4) The grain.
(5) The keeping qualities.

Development Time. The more a developer is diluted, the lower its activity (because of the lower concentration of the developing agents and alkali), and the longer the development time. Concentrated developers are therefore used where speed is important, and diluted solutions where the development rate is less vital, as in tank or stand development.

The increase in development time with dilution depends on the nature of the developer.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

With standard M.Q. carbonate developers the time is proportional to dilution around the ideal concentration. However, the time increases more at higher dilutions and decreases less at much higher concentrations. With the buffered type of formulae the development time does not change so much with dilution. Thus with some fine grain developers of this kind a ten-fold dilution of the standard working solution may only result in treble the development time.

Contrast. In addition to the effect on development time, dilution tends to reduce the contrast obtainable. This is important with materials that are more or less developed to finality such as printing papers. The reason is that at higher dilutions the development rate falls off more rapidly as development progresses, than at lower dilutions where the development rate tends to be more constant.

Contrast developers are therefore used in more concentrated solutions than standard developers.

Exhaustion. At higher dilutions the exhaustion of the developer tends to be more complete than at lower dilutions. In practice that means that a smaller amount of stock solution can be used per film or other unit area of sensitive material in tank development with highly diluted developer. This method of development is therefore more economical than development with more concentrated solutions which are generally discarded long before they are exhausted.

The limit to the useful degree of dilution is set by the minimum amount of developing agents in the solution required per unit area of the material. When operating near or below this limit there is a risk that the working solution will exhaust itself before development has gone far enough, or at least that the activity will drop so much during development that the action cannot be accurately controlled.

Grain. Owing to the reduced activity of a diluted developer, the grain obtained is finer. In practice this is, however, not the ideal way of producing fine grain images, because it also gives lower contrast. The decrease in graininess is not very great if the image is developed to a higher contrast.

Keeping Qualities. Dilution seriously shortens the storage life of a developer. This is because of the lower concentration of preservative in the dilute solutions and because a given amount of oxidation makes proportionally greater inroads into the concentration of the developing agents. This is the main reason (apart from convenience) why developers are stored in concentrated stock solutions. After use, a diluted working solution is best discarded.

EXHAUSTION OF DEVELOPERS

The number of negatives or prints which a given amount of developer solution will develop depends on: the composition and concentration of the developer, the area of the emulsion surface (i.e., the negative or print size), and the density of the image developed (a dense negative or print takes more out of the solution than a thin one).

The combined effect of all these variables can be found out only by experience.

Negative Developers. The list below gives the developer requirements for typical batches of plates of various sizes when developed in a dish.

If the plates are developed one after the other the development time will have to be increased by about 5 per cent for each plate.

With normal tank developers made up by diluting concentrated stock solutions, allow about 16–20 ounces (400–500 c.cm.) per standard film of 70 sq. ins. (450 sq. cm.). Use the working solution once only. This film area corresponds approximately to an 8-exposure ($2\frac{1}{4} \times 3\frac{1}{4}$ ins. or 6 × 9 cm.) length of roll film or a 36-exposure length of 35 mm. film.

AMOUNT OF DEVELOPER REQUIRED

Batch	*Amount of Working Solution*
4 plates, $2\frac{1}{4} \times 3\frac{1}{4}$ ins. (6 × 9 cm.)	3–4 ounces (80–100 c.cm.
2 quarter-plates, $3\frac{1}{4} \times 4\frac{1}{4}$ ins. (9 × 12 cm.)	
2 half-plates, $4\frac{3}{4} \times 6\frac{1}{2}$ ins. (13 × 18 cm.)	6–8 ounces (160–200 c.cm.)
2 whole-plates, $6\frac{1}{2} \times 8\frac{1}{2}$ ins. (18 × 24 cm.)	12–16 ounces (320–400 c.cm.)

For tank development in a small capacity tank, allow about 5–7 ounces (140–200 c.cm.) of working solution. Use once only.

With concentrated fine grain tank developers of the metol-hydroquinone-borax and other types of similar concentration, 16–20 ounces (400–500 c.cm.) will develop about two to four standard films. Again, the time has to be increased by about 5–10 per cent for each film developed.

With fine grain developers and commercial tank developers used in large bulk processing tanks replenishers can be added to make up for the lost developer activity.

Print Developers. When print developers are exhausted the image colour of the print may suffer and the longer development times necessary will cause staining of the paper.

The number of prints an average negative developer will develop depends on the size of the prints, as well as on the developer concentration.

Contact paper developers are generally used in comparatively strong solutions and they will usually do more work for a given volume than the weaker solutions used for enlarging papers. The exact exhaustion also depends on the proportion of dark tones in the prints; dark prints use up more developer than light ones. When a bromide or contact paper developer is

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

AVERAGE EXHAUSTION DATA FOR DEVELOPERS

Print Size ins.	Print Size cm.	Approximate Number of Prints Developed by: *10 ounces (250–300 c.cm.) of Bromide Paper Developer	*20 ounces (500–600 c.cm.) of Bromide Paper Developer
2½ × 2½	6 × 6	50	100
2½ × 3½	6 × 9	35	70
3½ × 4½	9 × 12	18	35
3½ × 5½	9 × 14	15	30

6½ × 8½	16 × 21	6	12
7 × 9½	18 × 24	3–4	7
8 × 10	20 × 25	3–4	7
10 × 12	25 × 30	2–3	5
12 × 15	30 × 38	—	3–4

*Only half this amount applies when using Contact Developer.

nearly exhausted the image-tones appear greenish-black, even after full development.

Once developer has been used, it does not keep well and should be thrown away. For economical working, prints are best planned in batches just large enough for each lot of developer made up. For this reason it is economical to deal with prints in uniform batches and to make up just sufficient developer to do one batch at a time. L.A.M.

DEVELOPERS (OBSOLETE). A number of developing agents which were popular around fifty years ago have now fallen into disuse. Of these, the main agents are ferrous oxalate, edinol, eikonogen, metoquinone and ortol.

Ferrous Oxalate. This is the only inorganic developing agent which has ever been used to any great extent in practice. It is a clean-working developer which produces hardly any fog, but it is very sensitive to the presence of potassium bromide which materially decreases the effective emulsion speed. The developing agent itself, FeC_2O_4, is invariably prepared in solution by mixing ferrous sulphate with an excess amount of potassium oxlate solution:

A. Ferrous sulphate	5 ounces	125 grams
Sulphuric acid, 10 per cent solution	290 minims	15 c.cm.
(or citric acid	10 grains	1·2 grams)
Distilled water to make	20 ounces	500 c.cm.
B. Potassium oxalate (neutral)	10 ounces	250 grams
Distilled water to make	40 ounces	1,000 c.cm.

For use pour 1 part of A slowly into 3 parts of B, stirring well all the time. If the solutions are mixed the other way round, a yellow precipitate of ferrous oxalate is formed. This is insoluble in plain water and soluble only in potassium oxalate solution; once formed it is very difficult to dissolve.

A white deposit of calcium oxalate may be produced in the emulsion during fixing or washing if the water for the latter processes is hard. The deposit can be removed by a final rinse in a 0·5 per cent hydrochloric acid solution.

Edinol. Para-aminosaligenin, $NH_2C_6H_3OH.CH_2OH$. This is a derivative of para-aminophenol which it resembles in its action. It is fairly soft-working, and can be used as a developer with sulphite and carbonate. A suitable formula is:

Sodium sulphite, anhydrous	5 ounces	125 gram
Edinol	½ ounce	12 grams
Sodium carbonate, anhydrous	1½ ounces	37 grams
Water to make	40 ounces	1,000 c.cm.s

Eikonogen. Sodium 1-amino-2-naphthol-6-sulphonate, $NH_2C_{10}H_5OH.SO_3Na$. This is a derivative of ortho-aminonaphthol, and resembles metol to some extent. A related substance, 1-amino-2-naphthol-4-sulphonic acid, has also been used as a developing agent. Eikonogen can be used either by itself with sulphite and alkali in the same way as metol, or combined with other developing agents such as hydroquinone or pyro. A suitable eikonogen formula is:

Sodium sulphite, anhydrous	2 ounces	50 grams
Sodium carbonate, anhydrous	¾ ounce	19 grams
Eikonogen	1 ounce	25 grams
Water to make	40 ounces	1,000 c.cm.

Metoquinone. $(CH_3NH.C_6H_4OH)_2.C_6H_4(OH)_2$. This is a condensation product of 2 parts metol with 1 part hydroquinone. On dissolving in an alkaline solution of sulphite it acts like a metol-hydroquinone developer containing the two developing agents in a proportion of 2 : 1.

Ortol. $(NH_2C_6H_4OH)_2.C_6H_4(OH)_2$. This is a condensation product of 2 parts ortho-aminophenol with 1 part hydroquinone. A suitable formula for a concentrated developer is:

Potassium metabisulphite	¼ ounce	7 grams
Sodium sulphite, anhydrous	1½ ounces	37 grams
Sodium carbonate, anhydrous	1 ounce	25 grams
Ortol	½ ounce	12 grams
Water to make	40 ounces	1,000 c.cm.

For use dilute 1 part of the above with 10 parts of water. L.A.M.

DEVELOPER TESTING. A developer is tested (as distinct from analysing it) by observing the behaviour of a sensitive emulsion developed in it, and possibly by comparing

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

this with the behaviour of another developer-emulsion combination. Such tests are carried out to plot time-gamma curves and establish sensitometric data and to obtain information about graininess, image structure and type, effect of variations of concentration, effect of different ingredients, temperature factors, etc. Much of this data is mainly of interest in the laboratory, and the testing procedures are laboratory methods.

Developer tests which a photographer is likely to want to carry out himself, may include:

(1) Comparison of contrast and rate of action of different developers and establishing an optimum development time for a new formula.

(2) Comparison of effective emulsion speed of different developers, or one developer at different development times.

(3) Comparison of graininess with different developers.

Basic Test Procedure. The practical part of most tests follows the same lines:

(1) Prepare two or more series of test exposures on a standard film. Each series should cover about seven exposures from one-eighth correct to eight times correct exposure. The subject should be one with a fairly long scale of tones from a reasonable amount of shadows to bright highlights; an indoor scene lit by lamps is best as it is easily reproducible and will not change in brightness with the weather. A suitable mark—e.g., a card with numbers which are changed for every shot—will help to identify the exposures given.

One good way of making the series is to use a 35 mm. miniature camera, and shoot off about three series on one cassette load, leaving a suitable number of empty frames between each set. The film can then be cut up at these empty frames before development.

As few cameras have really accurate shutters, the exposure for each shot of a series is best controlled by changing the aperture, keeping the shutter speed constant.

All the strips for a set of tests should be exposed at the same time.

(2) Develop one of the series or strips in a standard developer under standard conditions. This will serve as control.

(3) Develop the other series or strips in the developers, or the conditions, to be tested.

The evaluation of the results depends on the purpose for which the test is required.

Establishing Development Times. For this purpose a fair number of test series are required. If an approximate development time is known, a single test stage will give the necessary information; otherwise the test involves two stages.

To find an approximate time, first develop, say, five exposure sets for varying times. The range of times chosen will depend on the type of developer. For instance, a rapid developer with a medium speed film might be given times from 6 to 12 minutes, or a normal fine grain developer from 15 to 30 minutes. There should be a constant difference between the sets; thus the first set would be developed for 15 minutes, the second for 18, the third for 21 and so on.

Examination of the developed strips for contrast will then show which is nearest the correct time.

The negative selected should be the one which has received the minimum correct exposure—i.e., in which the shadow detail is just visible in the image.

To some extent the judgment will be arbitrary, and it may be desirable to make enlargerments from the best negative to see whethe-the gradation is suitable for the paper and printing procedure to be used. Comparison with the control strip will also help.

All processing temperatures must, of course, be the same, and each strip should be developed in fresh developer, preferably diluted from the same batch of stock solution.

Comparison of Effective Emulsion Speed. This type of test may be useful for investigating the merits of finality development or claims for increased emulsion speed with maximum energy developers.

Here again a control strip is developed in a standard formula, while the other strips are developed in the formula to be tested. When investigating finality development, the test series is developed in the same solution as the control, but for an appropriately longer time.

To assess the gain in speed, the negatives corresponding to minimum correct exposure in the control and the test series should be compared. If these negatives have received the same exposure, the gain is obviously nil; where, say, the first correct negative in the control set corresponds to f 5·6 and in the test set to f 8, the gain is 1 stop, or 100 per cent. Intermediate stages can generally be judged by estimation.

Comparison of Graininess. Here the control strip is compared with a strip developed in the test developer for an optimum time as established separately. If that is not possible, the comparison strip is developed for a time recommended by the makers of the film or developer. The control developer should be a standard fine grain—e.g., M.Q. borax—formula, while the film should be a high speed coarse-grained type.

The negatives corresponding to the minimum correct exposure on each strip are compared for graininess. For this purpose, 20-diameter enlargements are made of a portion of the image which shows typical highlights, middle tones and shadows. The paper used should be a normal grade, glossy bromide paper in both cases; the control as well as the test film must therefore be developed to a suitable contrast for this paper grade.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

It is important also to avoid enlargement of the image, as that will immediately destroy the definition of the graininess in the print.

Comparison of Definition. While the main factors determining the definition and resolution of an image are the optical system and the sensitive material, the developer employed does exert some influence. So does the degree of development. Thus if the image is developed mainly in the surface of the emulsion layer, the degree of spreading due to diffusion and irradiation is less than if the developer develops up the image throughout the depth of the layer (or if development is continued sufficiently long for the image to be developed in depth).

To test developers for their performance in this respect, the film selected is exposed to a standard resolution test target under specific conditions and different samples of the film so exposed developed under various conditions.

Resolution of the image can then be obtained by establishing the highest frequency of the test target still resolved (in lines per mm.) or by measuring the acutance of samples exposed for an acutance test.

If the test exposure contains images of resolution targets of different contrast or of a sinusoidal test target it becomes possible to plot a contrast transfer function of the developer-film combination. This transfer function of course also takes into account the performance of the optical system employed, but if all conditions are standardized apart from the developer, a comparison of the different transfer function curves shows up the differences in the definition performance of the developer.

A simpler and purely qualitative method of comparing the image definition obtained with different developers consists of exposing samples of a film to the image of a high contrast grid pattern. This consists of 20 to 40 lines per mm. with spaces between the lines equal to the line width itself. The comparison then merely involves a density measurement of sample areas of the image on the different films. These areas must correspond to similar positions in the image field.

The theory behind this method is that if the image on the film consists of very dense lines and virtually clear intervals, the integrated density reading is lower, the sharper the grid image is on the film. In theory completely opaque lines and completely transparent intervals should give an integrated density reading of 0·3 (in other words 50 per cent transmission). If the image is not perfectly sharp, the black lines tend to spread on the film, giving a higher integrated density reading.

While no silver image is ever completely opaque, this method still works in practice if the density difference between the black lines and the intervals is at least 2·0 and the fog density kept below a certain minimum level. The integrated density reading reflects both the resolution and the micro-contrast of the image, and so gives an indication of visual sharpness rather than pure resolution. This property, like acutance, is of practical significance. L.A.M.

DEVELOPING AGENT. Chemically, a developing agent is a reducing agent (not to be confused with a photographic reducer, used for decreasing the density of the silver image).

Developing agents can be classified according to their individual chemical properties, and to the way they behave in developers. The behaviour of any particular developing agent depends on the other ingredients present. Those affect its keeping quality, activity, and fine grain properties. So from a practical point of view it is better to consider the more common developer formulae and their agents at the same time.

Keeping Quality. Most developing agents are more rapidly oxidized in strongly alkaline solutions than in weakly alkaline or neutral ones.

Apart from this, however, some developing agents tend to keep better in solution than others, while some do not keep at all.

Development Speed. This depends largely on the alkalinity of the solution, the amount of restrainer, and the concentration of the developing agent. A table showing the inherent activity of various developing agents, is on pages 406–7.

The Watkins Factor does, however, offer a more accurate and less variable basis for comparing development speeds.

Effect on Emulsion. Some developing agents tend to produce images of low gamma while others are more suitable for use in high contrast developers giving high gamma.

The function of a developer should be only to act on the silver salts that have been exposed to light.

Unfortunately, most developing agents also affect unexposed silver salts, producing a silver deposit which has nothing to do with the photographic image. This is known as fog.

Much of the inherent tendency of a developer to form a fog depends on the developing agent. It is counteracted by adding a restrainer or a developer improver. The greater the fog formation, the more restrainer is needed.

The graininess in an emulsion is to some extent proportional to the activity of the agent. Low energy agents tend to make better fine grain developers. But with a suitable formula of controlled alkalinity and activity almost any developing agent can be used in a fine grain developer.

Effect of Temperature. The warmer the developer solution, the more rapidly it acts. The increase in development speed with temperature varies with the different developing agents. This sensitivity to temperature is stated in terms of a temperature coefficient. This is the ratio of the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

development times at two temperatures differing by 10° C. (18° F.). Thus, if a developer takes 7½ minutes at 24° C. to develop a given film, and 15 minutes at 14° C. to give the same result, the ratio is 15/7½, or 2·0. This is the temperature coefficient for that particular developer. The coefficient also depends to some extent on the composition of the whole developer. A normal value is about 1·8–2·2.

Developers also deteriorate more rapidly at higher temperatures, hence a developer solution should be kept cool. Some developing agents become virtually inactive at low temperatures.

Solubility. All developers contain the developing agent in solution, and most agents are soluble in water. Some are almost insoluble in water alone, and will dissolve only if the formula also contains alkali. Other agents (e.g., metol) will not dissolve readily if the solution already contains a lot of sodium sulphite. So metol is always dissolved in pure water and the sulphite added afterwards. Sometimes alcohol is added to the solution to increase the solubility of the developing agent. L.A.M.

DEVELOPING NEGATIVES

During exposure the light falling on the sensitive material affects the silver salts in the emulsion and forms a latent image. This latent image reacts with the developer during the development process which converts it into black visible silver.

This silver forms the final image which remains after the unused silver salts are dissolved and washed away in the fixing and washing baths that follow development.

There are two main methods of developing films and plates: by inspection or by time and temperature.

For the first, the material is usually developed in a dish in the darkroom by a suitable darkroom safelight.

For time and temperature development a dish may still be used; but it is usually more convenient to use a tank, particularly with roll and miniature films.

INSPECTION

This is the oldest way of developing plates or films. The sensitized material is immersed, emulsion up, in a dish of developer, and watched as the image appears. This is often called dish development.

It must be done by the light of a suitable safelight. High speed panchromatic materials are sensitive to even the dimmest darkroom safelight, and must only be examined intermittently.

Desensitizers can be used to lower the sensitivity of the emulsion and allow brighter safelights to be used.

Inspection development is comparatively little used in modern commercial processing. It does however demonstrate visibly the progress of development and permits a certain degree of control in special cases.

The method is primary suitable for plates and sheet films (which are handled largely in the same way).

Plates. As soon as the plate is in the developer the dish is gently rocked to keep the solution moving over the surface. For the first few moments (or minutes, with a slow working developer) there is a delay (the induction period) during which the solution penetrates into the gelatin layer.

Then, gradually, signs of the image begin to appear.

At first only the parts which have received the most exposure (the highlights in the negative) show up. Then the medium tones follow, and finally the shadows where the deposit of black metallic silver is least.

The image builds up density, and gets darker and darker, until no details are visible on the face of the plate as it lies in the dish. But when the plate is looked at from the back, the highlights and half tones appear black and dark grey, with the shadows light grey.

At this point development is complete. The plate is rinsed in clean water, and transferred to the fixing bath.

As long as the greater part of the image still looks white or light grey from the back, the negative is under-developed. If the plate is completely black all over it is over-developed.

The ability to judge the correct degree of development by the dim darkroom illumination comes from practice. As development tends to start at the surface, the first deposit of silver completely hides what is happening underneath.

But if the back of the plate is examined, the gradual building up of the image is easy to follow.

This process of depth development does not occur with some of the fine grain developers. With such developers examination of the unfixed negative from the back may be misleading. These developers are, however, rarely used for processing by inspection.

The complete steps in processing plates and sheet films by inspection are as follows:

(1) Immerse the plate or film, face up, in the dish of developer, making sure that the solution covers the whole surface at once.

(2) Dislodge any airbells from the surface of the emulsion.

(3) Rock the dish gently, but not too evenly, all the time.

(4) Inspect the negative from time to time,

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

PROGRESS OF DEVELOPMENT. Development in most developers begins at the surface of the emulsion and progresses downwards with increasing development time.

lifting it out to see the image from the back, if necessary. Keep the dish covered with a card at all other times, and do not prolong the inspection, especially with fast panchromatic plates.

(5) When development has reached the required point, transfer the film or plate to a dish of clean water for 1 minute.

(6) Transfer the negative to the fixer.

(7) Rock the fixing dish occasionally, and leave the negative in it for about twice as long as the time required to discharge all traces of milkiness from the emulsion layer.

(8) Wash the negatives in running water for at least thirty minutes, or in eight changes of water of three to five minutes each. With plates take care they do not slide over each other in the washing dish.

(9) Lift the plates out of the washing water, drain, and stand up on edge in a dust-free place to dry. Alternatively, stand the plates in a drying rack. Sheet films should be hung up on a line by means of small film clips.

Rollfilms. Strips of roll film can in principle be developed in a similar way, by see-sawing the film through the developing dish. This method is, however, highly inconvenient and of no advantage over tank development, since individual control of negatives on the roll is impractical.

Control of Contrast. Development by inspection allows a certain degree of control over the final result. The length of development determines the contrast as well as the density of the negative.

While it is difficult, if not impossible, to judge the contrast of a negative by safelight illumination, watching the negative density will give some idea of the progress of development.

Negatives can therefore be developed individually to different degrees of contrast to suit the subject, provided the exposure has been reasonably correct in the first place.

But to get the highest contrast it is better to use a contrast developer and to reduce the contrast of a contrasty subject it is better to use a soft developer or some kind of water-bath or two-bath development. These methods give the required contrast compensation without the excessive density produced by over-development, or the thinness which results from greatly reduced development.

Factorial Development. At a time when development tanks were still relatively unknown, photographers tried to put inspection development on a slightly more scientific basis. At the end of the last century A. Watkins showed that there was a relationship between the time of the first appearance of the image and the total time of development for approximately correct negatives. He found that the time of development could be calculated by noting the time it took for an image to appear and multiplying that by a factor. The so-called Watkins factor depends on the developer, but—within limits—neither on the temperature nor on the concentration of the developer, nor on the negative material. This method of development is known as factorial development. The Watkins factors vary from 4–5 for developers of the hydroquinone type to around 30 for metol.

Factorial development gives correct results only with correctly exposed negatives. Since modern films and plates contain sensitizing dyes which may affect the factor unpredictably, this method is not nowadays a very reliable one.

SEE-SAW DEVELOPMENT. The two ends of the film are alternately lowered and raised so that the bottom of the loop passes continually through the solution.

TIME AND TEMPERATURE

For any one film-developer combination the degree of development (under conditions of standard agitation) depends only on the temperature of the developer and on the time during which it is allowed to act. So if a film is developed in a given developer for a specified time and at a specified temperature, the resulting negatives will always be of the same quality. This system of time and temperature development is the basis of all modern tank procedures. With amateur tanks neither darkroom nor safelight is needed, since the tank is light tight and all operations—except for loading of the film—can be carried out in broad daylight.

Development Times. The various manufacturers recommend development times for their

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

materials in certain standard developers. These times are intended mainly as a guide, rather than as absolutely correct values. There is in fact no such thing as one correct development time; apart from variables such as agitation, etc., a great deal also depends on personal preference. For instance, some photographers may prefer comparatively thin negatives of low contrast which will enlarge well on a hard paper grade and need only short enlarging exposures; others again favour more vigorous negatives (especially when they are to be printed by contact). The range of correct development times is thus rather wide; comparison of different recommendations for essentially similar developers and negative materials may show variations of up to 100 per cent.

For that reason no development times are given here. The best procedure for establishing a suitable development time for a given developer-film combination is therefore to start from the maker's recommended figure, and modify it according to individual requirements. If the negatives turn out too contrasty the time can be reduced by 20–30 per cent; if they are too soft for the particular printing procedure employed, increase the time up to 50 per cent.

A number of variable factors have a bearing on the correct time of development: negative contrast; negative material; temperature; agitation.

Negative Contrast. The negative contrast aimed at is decided partly by personal taste, and partly by the printing process to be used.

Apart from individual preferences, miniature negatives are usually developed to a lower contrast (about gamma 0·7–0·8) than larger negatives (gamma 0·9–1·0). The reason for this is partly the finer grain obtained with shortened development, and partly the fact that fully developed negatives are denser and may require inconveniently long enlarging times. In addition a certain amount of contrast control may be desirable with a roll of film consisting of exposures of the same or similar subjects.

DEGREE OF DEVELOPMENT. *The longer the developing time, the blacker the densities become. They increase in proportion to the original exposure, yielding successively a soft, normal, and contrasty image of increasing tone separation.*

Negative Material. Different negative materials require different development times; some develop more slowly, others more rapidly. It is usual to divide negative materials into a number of development groups. Times are then quoted for materials of normal development speed, and modified accordingly for materials in any of the other groups.

Temperature. The temperature effect varies with the type of developer and is expressed as a temperature coefficient. This is the factor by which the development time has to be multiplied for a fall of 10° C. (18° F.) in the development temperature.

For most developers the temperature coefficient is in the neighbourhood of 1·9, though it may be as low as 1·5 or as high as 2·5. Strongly alkaline developers of the high contrast type such as caustic hydroquinone have high temperature coefficients. On the other hand, soft working developers like metol are much less affected by changes in temperature.

The useful range of development temperatures is about 60–75° F. (15–24° C.). At temperatures lower than 60° F. development times are inconveniently long; above 75° F. the gelatin emulsion becomes soft, and extra care is needed in handling the film to avoid injury to the gelatin. In fact, the use of hardeners or even special hot weather processing is advisable at high temperatures.

The table below gives the variations in development time for an average developer.

DEVELOPMENT TIMES AT VARIOUS TEMPERATURES

Time in Minutes at 65°F. (18·4°C.)	*Corresponding Time in Minutes at* 60°F. (15·5°C.)	62·5°F. (17°C.)	68°F. (20°C.)	70°F. (21°C.)	75°F. (24°C.)

Agitation. By agitating the film in the developer, fresh solution is brought into contact with the emulsion, while the used-up solution is carried away and mixed up with the bulk of the developer in the dish or tank.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The film may be agitated all the time, or only intermittently. Constant agitation keeps the solution always on the move. It is essential with certain types of developing tank where the film is only partly immersed in the solution.

See-sawing a length of film through the solution is also a form of constant agitation for roll films.

In bulk processing tanks the solution is often agitated by a mechanical mixing device.

Intermittent agitation means agitation for a few seconds every two to three minutes. The solution is not mixed up as efficiently, therefore the film needs a longer development time. Usually the instructions with the developer quote the times for intermittent agitation; for constant agitation they can be shortened by 25–30 per cent.

Insufficient agitation (with intervals of more than about four to five minutes) may cause streaks of uneven density, light rims round dark image areas or dark areas with lighter spots in the centre.

Some degree of regular agitation during development is therefore essential. The shorter the over-all development time for the particular film and developer used, the greater the danger of uneven action through insufficient agitation.

With high speed developers and similar formulae the solution must never be allowed to stand still.

Too regular agitation may cause flow marks when partly exhausted developer flows over the emulsion surface in the same way and the same direction all the time, e.g., by rocking the dish or rotating the film reel always with the same motion. The developer dish, or film reel, should therefore be moved unevenly in all directions. If the film can be raised out of the solution and allowed to drain from time to time, so much the better.

Special Developing Techniques. The normal standard development technique serves on most occasions, but occasionally it does not bring out some particular aspect of the subject, or it does not make the most of a subject with some abnormal feature about it—e.g., extreme contrast or flatness. In such cases it is often possible to apply one of the many variations of the standard developing technique, although usually what is gained in one direction is lost in others. (The debit side of the balance is frequently overlooked, an oversight which is responsible for many exaggerated claims for unorthodox techniques or developers.)

There are, for example, non-standard techniques which aim at increasing film speed, improving grain, adjusting tone range, contrast, printing quality, etc. The commoner variants are development to finality, stand development, high speed development, two-bath and water-bath development, and the use of special forebaths.

TANK DEVELOPMENT

Most types of developing tank for amateur use consist of a light-tight container (usually made of black bakelite or other plastic) with some sort of holder inside for the films and plates.

Most roll film and 35 mm. film tanks carry the film wound up on a reel which may either be a spiral type or a reel with an apron.

Types of Tank. The spiral tank reel consists of two discs connected by a hollow spindle; a spiral groove runs on the inside faces of each disc until it reaches the spindle at the centre. The film is loaded into this spiral groove, which is the exact length to accommodate the entire film. Sometimes, the separation of the discs is adjustable so that films of different sizes (widths) can be processed.

Tanks are also made which allow the film to be loaded in daylight.

The basic construction of the apron tank is similar, except that the reel has no spiral groves. Instead, a celluloid or plastic band the same width as the film attaches to the centre spindle; the edges of this band have raised "dimples" embossed in alternate directions. The film is wound on to the spindle with the embossed band, the "dimples" of which touch the film at the edges only.

Some roll film and 35 mm. tanks are of the self-loading spiral type. In these tanks the cheeks on the reel can be moved through a small angle in relation to each other; the grooves are either moulded with projections which grip the film in one direction only, or the necessary one-way pressure is applied with the fingers. By turning the loose cheek to and fro, the film automatically feeds itself on to the reel once started in the spiral.

Most modern spiral reel tanks have cheeks of transparent plastic. This simplifies the reversal exposure when processing reversal colour films, making it unnecessary to remove the film from the tank reel. Otherwise reloading a wet film into a wet reel is tricky and liable to damage the film itself. Reloading a wet film into an apron tank is easier.

Plate and sheet film tanks are simple rectangular boxes with vertical grooves inside the body (sometimes as a removable rack) into which the plates or films are loaded. Sheet films are first loaded into stiff frames for rigidity.

Loading Spiral Tanks. The operations must be carried out in the dark. Their sequence is as follows:

(1) Prepare the film end.

(2) Feed the film into the beginning of the groove.

(3) Gradually push the film into the reel.

(4) Detach from backing paper or cassette spool.

(5) Put the reel into the tank.

After unrolling the beginning of the backing

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

LOADING A ROLL FILM TANK. 1. *Break the seal of the roll and unwind the backing paper (in total darkness) until the end of the film itself is reached.* 2. *Unroll a little more to have about 3–4 ins. free (but hold the spool to prevent it from unwinding altogether).* 3. *Guide the end of the film into the mouth of the spiral groove of the tank reel.* 4. *Feed the film into the reel until the other end (attached to the backing paper) is reached. A self-loading tank reel with rotating flanges greatly simplifies this operation.* 5. *Detach the film from the backing paper and push the last bit into the reel.*

paper, the film end may be prepared by bending in the extreme edge and sharply folding it back on itself. That gives the film a reinforced leading edge which is not so likely to stick in the groove. This trick is useful with roll films which are comparatively thin (3/1000 in.), but less necessary with the thicker 35 mm. films (5/1000 in.).

With 35 mm. film the specially shaped leader or trailer must be cut off.

The prepared end is pushed into the entrance of the spiral groove. (The reel must be absolutely dry, or the film may stick in the groove.)

The film is then fed into the groove gradually, bit by bit, unrolling the backing paper or pulling the film out of the cassette at the same time. If the going becomes difficult, the best way is to grip the outside of the film already on the reel with the whole hand, and gently rotate it to pull more film into the groove.

When all the film is on the reel, the other end must be detached from the backing paper. The tape with which the two are fastened should not stay on the film. With 35 mm. film the end is simply cut off as near to the cassette spool as possible.

Finally the last bit of film is pushed into the groove, the reel inserted into the tank body, and the lid closed.

There is also an alternative method. Here only the first few inches of the film are fed into the groove. The part of the film just outside the reel is then gently arched by pressing the two edges together.

While rotating the reel in the loading direction the leading end of the film is pushed right into the centre of the reel. The arched part of the film will then jump across the grooves. Where the reel has projecting lips at the entrance to the groove (as on some older designs of reel) the film must be eased past them at each revolution.

The reel is now rotated in the opposite direction, and as each part of the film reaches the inside of the spiral the pressure which holds it arched is released and it slips easily into the groove.

With a self-loading tank the procedure is simplified, as it is only necessary to feed the beginning of the film into the groove. After that the self-loading mechanism takes over.

When the whole film is wound up in this way, the end is detached from the backing paper or cassette spool, pushed into the groove, and the reel inserted into the tank.

Loading Apron Tanks. To load an apron tank, the apron is first clipped to the centre spindle of the reel. The end of the film is then pushed under the same clip and the two are drawn around the spindle by rotating the reel.

When the film has wound on to the end, the backing paper or film cassette is cut away and the reel is rotated until the end of the apron is reached. This carries a clip by which it is

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

secured to the rim of the spool. The reel is then dropped into the tank, the lid is fitted, and the rest of the operations can be carried out in daylight.

Loading Daylight Tanks. Each make of tank has its own method of loading, the differences lying mainly in the method of transferring the film from its spool or cassette on to the reel. The safest guide is to follow the usually very detailed maker's instructions.

Loading Plate and Sheet Film Tanks. According to the design of the tank, plates have to be fitted into the grooves of a plate rack, or into the tank itself. The important thing is to get each plate squarely into the right pair of grooves in the dark.

With some plate tanks a special loading jig is supplied. The jig is placed over the top of the plate rack or over the tank opening, when two guides on the jig align it with the correct grooves of the tank. The plates are then simply inserted through slits in the jig.

Sheet film is usually held in a frame made of stainless steel and then treated like a plate.

There are also special sheet film tanks, mainly to cater for the larger sizes of sheet film. Here again the film is inserted into stiff frame-like hangers. These are then suspended in a large rectangular tank of suitable size.

Processing in Tanks. Assuming the tank to be loaded with film or plates, the procedure is:

(1) Pour the developer into the tank.
(2) Agitate.
(3) Develop for the required time.
(4) Pour in rinse.
(5) Pour in first fixing bath.
(6) Pour in second fixing bath (if used).
(7) Wash.
(8) Remove from tank.
(9) Dry.

(1) The right amount of developer for the tank at the right temperature (between 60 and 75° F. or between 15 and 24° C.), prepared beforehand, is poured into the tank. A funnel is not necessary because most tanks already have funnel-shaped openings in the lid. The time when the developer is poured in is noted.

(2) Agitation should start as soon as the developer is in the tank. Normally that involves inverting the tank a few times—after closing the centre aperture. (Tanks have a special rod that is inserted through the centre opening and engages with the hollow spindle of the reel. This allows the reel to be rotated. Plate tanks have to be rocked or shaken.)

(3) Throughout the whole development period a close watch is kept on the temperature of the solution. It must not be allowed to vary more than a degree or so.

(4) The solution is agitated for about ten seconds every other minute and at the end of the development period it is poured out and the tank is immediately filled with water at the same temperature. Instead of washing water, a stop bath and a hardener may be used.

DEVELOPING FILMS. 1. Load the film into the tank, then pour in the developer. 2. Agitate the reel inside the tank, vigorously at first, and then at regular intervals. 3. Develop for the time recommended at the temperature of the solution. 4. Pour out the developer. 5. Fill the tank with clean water or with an acid hardening rinse. 6. Pour out the rinse. 7. Pour in the fixer. 8. Fix for the required time, then pour out (the fixer can be re-used until exhausted). 9. Wash, preferably by running water, for at least ¾ hour. 10. Give a last rinse with wetting agent and, if needed, a few drops of acid added. 11. Wipe the film free from surplus water. 12. Hang up to dry.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

(5) The film is kept moving about in a minute and then the water is poured off and the fixing solution is poured in. The negatives are left in the fixer for at least ten minutes, again agitating periodically. It is then safe to open the tank and examine the film. When all the milkiness has gone from the film it should remain in the fixer for a further 10–15 minutes.

(6) A second bath of fresh fixer is often given to ensure really efficient fixation. The immersion time in this solution should be about ten minutes.

(7) The film or plates are then washed. The temperature of the washing water should be the same as that of the last fixing bath. Otherwise the temperature must be gradually reduced from the fixer to the washing water.

Roll films can be washed in the tank by passing a rubber tube from the water tap down the centre of the reel. Plates are best taken out of their tank and laid face up in a large dish, for most plate tanks do not allow efficient washing of the plates inside.

An alternative way of washing is to fill the tank with changes of fresh water, leaving it for 5 minutes each time. About six to eight such changes are sufficient.

After washing, the tank is filled with water again, and a few drops of wetting agent and, if necessary, dilute acetic or hydrochloric acid added.

(8) The film is then carefully unrolled from the reel, and a film clip fixed to each end. Most of the water can be removed by wiping it down but this entails some risk of scratching the wet emulsion. With plates the surplus water is best shaken off as far as possible.

(9) Finally, the films are hung up to dry in a dust-free place. Plates should be dried in special plate racks, while sheet films can be pinned up by one corner. L.A.M.

DEVELOPING PRINTS

Prints are invariably developed by inspection by being immersed flat and face up in a dish of developer. During the development of an exposed print the developing solution converts the invisible latent image in the sensitive emulsion into a visible picture. The developed print is rinsed, and then fixed to dissolve away the unused silver salts. Finally, all soluble chemicals left in the paper are washed out and the print is dried.

Developers. The best developer to use depends to some extent on the type of printing paper.

Chloride contact papers are best developed in a contact paper developer containing a comparatively low amount of potassium bromide.

Bromide and chlorobromide enlarging papers are developed in a standard paper developer. Some of these serve equally well for bromide, chlorobromide and contact papers.

For warm tones on chlorobromide, contact, or enlarging papers, warm tone developers and special development methods are required.

Prints are generally developed by inspection in the light of a suitable safelight.

Processing. The sequence of operations in developing a print is:

(1) The print is immersed in the developer in such a way that the solution flows rapidly over the whole surface of the print. Small prints are simply pushed under the surface of the solution with the print forceps. With larger prints a satisfactory method is first to raise one end of the developing dish, so that all the solution collects at the other end, then hold the print, face up, and push one edge into the liquid. Finally release the end of the dish and allow the solution to flow in a wave over the whole of the print surface. Any air bubbles are immediately broken up with the forceps.

(2) The developing dish is gently rocked by raising and lowering one edge to keep the solution moving over the paper. Any corners of the paper which curl out of the solution during the first few seconds are pushed under with the forceps.

(3) When a print has had too little exposure, the image shows up very late and fails to reach a satisfactory depth of tone, no matter how long it is left in the developer. When a print has had too much exposure, the image flashes up in a few seconds and soon becomes too dark. The print always looks slightly darker under the orange safelight than it will look under normal lighting. If the safelight is olive-green, there will be less difference between the appearance of the print as seen in the darkroom and its appearance when it is finished and viewed by normal lighting.

(4) Development is continued until the image does not seem to go any darker; this point is usually reached after about two minutes, but it will depend on the developer in use (and its temperature) and also the type of paper. The print is then lifted out of the solution with the forceps, drained, and dropped, face down, into the rinse dish. If a chemical stop-bath is used the forceps should not be allowed to come into contact with the solution when transferring the print.

(5) The print is moved about in the rinse for about a quarter of a minute. If a chemical stop-bath is used instead of a plain water rinse, a

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

DEVELOPING PRINTS. 1. Slide the exposed sheet of paper into the developer. 2. Rock the dish during development until the image is fully developed out. 3. Transfer the print into an acid stop bath. 4. Transfer the print to the fixing bath. Leave for about 5 minutes (moving it about regularly). White light can be turned on after this stage. 5. Wash in running water or in frequent changes of still water. 6. Hang up (large prints) or lay down on clean muslin to dry (prints can also be dried by hot or cold glazing on glossy paper).

separate pair of forceps should be used for handling the print in this bath and transferring it to the fixing bath.

(6) It is then lifted out, drained, and immersed, face down, in the fixing bath, where it is kept moving for about half a minute to make sure that the fixer reaches the whole print surface.

(7) When the print has been in the fixing bath for about a minute, the white light may be switched on, and the print examined. This will show whether the exposure was correct and whether the contrast is satisfactory. When further prints are immersed in the fixing bath, they should be pushed, face down, underneath the prints already there. The prints should be moved about from time to time to prevent them from sticking together and to bring them into contact with fresh solution.

(8) If two fixing baths are used, the print is lifted out of the first bath after about five minutes, and transferred to the second for the same length of time.

(9) Finally, the print is lifted out of the fixer and washed.

Rinse. The simplest rinse between development and fixing is plain water. This removes most of the developer from the prints before they pass to the fixing bath. It protects the fixer from excessive contamination and makes it last longer. The water should be changed frequently, as it, too, becomes contaminated with developer.

An acid rinse or stop-bath is better than plain water because it neutralizes the developer and arrests development in a second or two. And an acid rinse does not need to be changed as often as a plain water rinse.

The stop-bath may be a 5 per cent solution of potassium metabisulphite or sodium bisulphite, or a 2 per cent solution of citric or glacial acetic acid with about 1 per cent of sodium sulphite added.

Stronger stop-baths are not recommended, because they generate an appreciable amount of carbon dioxide gas in the emulsion when they react with the sodium carbonate of the developer. This gas may cause blisters on the print surface.

Development Time. The normal development time at 65–68° F. (18–20° C.) in one of the common paper developers is 45–60 seconds for chloride contact papers and 2–3 minutes for chlorobromide and bromide papers.

This is the minimum time the positive image needs to build up to its full depth of tone. Development usually takes more time in diluted solutions and less in strong solutions. With heavily restrained warm-tone developers, the development time with chlorobromide papers may be as much as half an hour.

Compensation in Development. When a print has been given too much or too little exposure, there is very little that can be done to put it right during development.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

With a normal type of chlorobromide paper, cutting short development to keep down the density of an over-exposed print usually flattens the contrasts and gives unpleasant greenish-black tones. The results of over-exposure can be improved by adding a restrainer or developer improver to the developer. But the print will never be as good as one that has been correctly exposed and fully developed.

Chlorobromide papers have more latitude, and development of over-exposed prints can be retarded by diluting the developer and adding a restrainer—e.g., potassium bromide. The development time is longer in a restrained and diluted developer, and can be stopped at any point. The shorter the development time under these conditions, the warmer the image tone. This method is therefore used in warm tone development and also to control density by three-dish development.

An under-exposed print is too light at the end of the normal development time, but the image is still gaining density (though very slowly); so slight under-exposure can be compensated by prolonging the development. This procedure often causes yellow developer stains on the paper, particularly if the developer contains a lot of hydroquinone.

Temperature. The best development temperature for papers is between 65 and 75° F. (18–24° C.). At temperatures below 60° F. (15° C.) the action of the developer is inconveniently slow; at temperatures above 75° F. (24° C.) the developer tends to stain the paper.

Variations of temperature between developer and rinse and between rinse and fixer do not matter as much as they do with films or plates; the emulsion is more firmly bonded to the paper base, and is not as likely to reticulate during processing.

Warm Tone Development. Chlorobromide papers developed in special warm tone developers can be made to yield a whole range of image tones from warm black to almost red. The tones depend on the make of paper and on the developer used, as well as on the relative exposure, dilution of developer, concentration of restrainer (potassium bromide or ammonium bromide) and development time.

The warm tone image has a much finer grain than the ordinary black tone image, although the graininess is not visible to the naked eye. During development, prints normally pass through the whole sequence of tones from reddish-brown to black, as they build up grain size and density.

In an energetic developer the transition of tones is too rapid, and by the time the image is dense enough to be acceptable, the grain size has already reached the point at which it gives black tones. By using a suitably diluted and restrained developer on the right kind of paper, the grain size can be kept down to the level that corresponds to the desired warmth of tone while density is built up. Chlorobromide papers are particularly suitable for this purpose, since they form an image from two different kinds of silver halide grains.

To compensate for the low density of the image at the warm tone stages, the exposure must be increased. The warmer the desired image tone, the more the exposure must be increased beyond normal.

So a warm tone image is one that has been over-exposed and then developed only until it reaches the right tone and density. This means that the relative exposure and development times have to be standardized if they are to produce exactly the desired image tone.

Exposure and Development. The exposure and development conditions must be determined separately for every developer-paper combination. This is best done by making comparative test strips.

First, an ordinary test strip is made on the chlorobromide paper, using a standard negative under set conditions of printing and processing. This test strip is fully developed—three minutes at 65–70° F. or 18–21° C.—in the warm tone developer. The developer is used at its normal concentration, corresponding to the coldest black it is capable of producing, without added potassium bromide. This strip is then used as a standard of reference to show the normal exposure required to give the nearest possible approach to a pure black-and-white print.

About half a dozen test strips are then prepared on the same paper. The exposure steps on each test strip are: normal (as found by the original strip), 1½, 2, 3, 4, 6, 9 and 12 times normal exposure. All six test strips are exposed under the same conditions, but developed separately in different concentrations of developer.

DEVELOPMENT OF TEST STRIPS

Strip	*Developer Dilution Times Normal*	*Extra Potassium Bromide (grams per 1,000 c.cm. working solution)*	*Development Time at 68°F. (20°C.)*
I	4	1·0	4½ minutes
II	8	1·5	8 minutes
III	12	1·5	12 minutes
IV	20	1·2	16 minutes
V	25	1·2	20 minutes
VI	30	1·2	25 minutes

This test strip series should show all image tones from warm black to the warmest the paper will give. If necessary, additional strips can be prepared to bridge any apparent gaps in the range.

The series also shows the exposure required to produce a print of the right density for each image tone.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

To make a print of any required tone, the normal exposure is first found in the usual way.

The test strip showing the desired image tone is then selected from the series. This strip says at once which developer dilution and time of development will give the desired tone. Then, by referring to the exposure scale on the strip, the exposure to give the required density at that image tone can be arrived at.

The range of tones obtained and the exposures and developer dilutions required vary for each paper-developer combination. A new set of tests is necessary whenever the developer or the paper is changed.

The contrast of the prints decreases as the warmth of the tone increases, and a harder contrast grade is advisable when producing very warm tones.

Large Prints. When prints are too large for a normal developing dish, they may be developed in one of the following ways: by see-sawing each print like a roll film; by carrying out all the processing in a single large dish; by applying the processing solutions with a swab or spray.

See-saw development is useful if the print is just too large to lie flat in the largest dish available. If the dish is a little longer than the print is wide, the print can be held by the two short edges and developed by see-sawing it through the various solutions. The dishes need be no more than narrow troughs, provided they are long enough, and are sufficiently deep to allow a good covering of developer.

Single-dish development calls for only one dish big enough to hold the print. This dish is used for all the processing steps.

When the print has been exposed, it is laid flat in the dish and the developer is poured over it. As soon as the print is fully developed, the solution is poured off into a jug, and the rinse or stop-bath is poured in. After rinsing thoroughly, the dish is drained and the fixer is poured in and left for the usual length of time. Finally, the print is removed for washing and the dish is rinsed ready for the next print. (There is no difficulty in washing large prints in the bath or kitchen sink.)

Swab and spray development are methods for really large prints, like those used for making photo murals. With prints of this size the developer and other solutions are swabbed or sprayed over the print, and the picture is fixed and washed by the same means.

Because the surface of the print is exposed to the air most of the time, easily oxidized developers—e.g., those containing a high concentration of hydroquinone and alkali—are not suitable, as they are apt to produce stains and aerial fog. The best developers are those like glycin which work cleanly.

TWO-BATH DEVELOPING AND STABILIZING UNIT. The prints pass along the dotted line between developing rollers, which carry the activating solution to the print surface, and then through a stabilizer solution. They emerge merely damp from the final squeegee rollers. A, developing rollers. B, activator. C, squeegee rollers. D, stabilizer.

Print Processing Machines. As an alternative method of print development the use of motorized processing machines is gaining popularity. These pass the exposed sheet of paper in succession through a developer and a stabilizing bath, to deliver a ready processed print within about ten seconds. Motor- or hand-driven rollers carry the print through the solutions in a double trough and eliminate the need for processing dishes and even print washing (the paper leaves the processing machine in a semi-damp state).

The use of machines of this kind frequently calls for special papers incorporating some of the developing chemicals. The developer solution then consists only of an alkaline activating bath which enables development to be complete within the time (a few seconds) it takes the paper to pass through the developer solution.

Paper prints and enlargements produced in this way are reasonably stable for some months and even years.

For maximum stability for archive purposes refixing in a normal fixing bath is advisable.

DEVELOPING TANK. Tank of plastic or stainless metal in which negative materials can usually be completely submerged in the developing solution for the period of development. Most developing tanks for amateur use are designed to permit all operations of processing (apart from the initial loading) to be carried out in normal light. Some even allow the loading to be done in daylight.

See also: *Tanks.*

DEVELOPMENT AFTER FIXING. During physical development an image is built up, by a process of silver intensification, on a very

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

weak silver image first formed by normal chemical development.

Very minute amounts of silver are, however, already formed during the original exposure. These may by themselves form a foundation for a physically developed image. This makes it possible to fix a negative after exposure and then develop it in a physical developer by ordinary daylight.

The effective emulsion speed of the film or plate is greatly reduced and negatives need about 3–4 times the normal exposure. Some modern negative materials fail to react satisfactorily to this method.

A suitable developer is:

Stock solution A				
Potassium thiocyanate	1	ounce	25	grams
Silver nitrate	70	grains	4	grams
Sodium sulphite, anhydrous	½	ounce	12·5	grams
Sodium thiosulphate (hypo) crystals	88	grains	5	grams
Potassium bromide, 1 per cent solution	96	minims	5	c.cm.
Distilled water to make	8	ounces	200	c.cm.

Dissolve the silver nitrate and sodium sulphite separately in the smallest possible amount of distilled water. Slowly stir the sodium sulphite into the silver nitrate solution. When the precipitate which forms at first has redissolved, add the thiocyanate and the hypo, and finally the potassium bromide. Make up to the final volume with distilled water.

Stock solution B				
Metol	27	grains	1·5	grams
Sodium sulphite, anhydrous	½	ounce	12·5	grams
Distilled water to make	4	ounces	100	c.cm.

Just before use, mix 6 parts of A, 1 part of B, and 23 parts of water. Instead of B a commercial concentrated single solution developer of the para-aminophenol type may be used.

Development is very slow, and may take several hours. Since it is easily watched, this is not inconvenient.

After development is complete, the negative should be washed in running water for at least half an hour. L.A.M.

Book: *Developing*, by C. I. Jacobson (London).

DEVELOPMENT CENTRE. Accumulation of silver atoms in a silver halide crystal formed by the action of light. Usually requires the presence of sensitivity specks in the crystal. The development centre or centres provide the point of attack for the developer to reduce the silver halide of the crystal to metallic silver and so form a visible image.

See also: *Latent image.*

DEVELOPMENT FOG. Fog formed by the development of unexposed grains of emulsion that occurs when the sensitized material is developed for too long a time or under unsuitable conditions.

See also: *Fogging; Fog level.*

DEVELOPMENT GROUP. Classification of a film according to its development time characteristics. Development groups are used in tables and calculators for working out the correct development time of any film with any developer. The group generally depends on the film speed, although there are exceptions when film-developer combinations behave in an unpredictable way. Thus such groupings are not infallible.

DEVELOPMENT HISTORY. Practicable photography began with the discovery of the phenomenon of development. Without the development process, all the energy needed to form a visible image must come from the light which falls on the sensitive surface during the exposure. In the absence of intense sources of illumination, far exceeding direct sunlight in power, prolonged exposures are necessary.

Although development is normally taken to cover only the conversion of latent images in silver halide into silver, N. Niépce used oil of lavender in 1822 to wash away the unexposed parts of his bitumen coatings.

The existence of a latent image and the possibility of its development at a later stage allows the image formation to be separated into two stages:

(1) The first stage, the exposure in the camera to form the latent image, requires very little energy and can be completed in a very short time.

(2) Almost all the work of forming the visible image is carried out in the development stage which can be postponed to a convenient time.

Development was discovered by Daguerre by a pure accident. Following some unsuccessful experiments during 1835, he placed an iodized silver plate in a cupboard. Some time later he found it bore a distinct image, though at the time when it was consigned to the cupboard it bore none. By a process of elimination he was able to attribute the image formation to the presence of mercury in the same cupboard. The mercury vapour had gradually condensed on the parts of the silver iodide which had been exposed in the camera.

In September 1840, Fox Talbot discovered how to develop a latent image on silver iodide paper using a solution of silver nitrate and gallic acid. He was enabled by this discovery to reduce his camera exposures from one hour to half a minute. This was, in fact, physical development.

In 1844, Robert Hunt introduced iron sulphate as a developer for silver halide paper materials and this developer played an important rôle in the early years of the collodion process of le Gray and Scott-Archer. Although pyrogallic acid, or pyrogallol, was shown by Regnault and Liebig to be an active developer and was suggested by Scott Archer himself for his process, the iron sulphate developer predominated for collodion wet plates.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Up to this time all development was of a physical character and was carried out in acid solution. Following the advent of the dry collodion plate, Mudd and Wardley found in 1861 that a plain ½ per cent solution of pyrogallol would serve as a good developer without the usual additions of silver nitrate and acid.

Alkaline Development. In 1862, Russell and Leahy discovered the bromided pyro-ammonia developer and thus initiated the alkaline "chemical" developer which was greatly to assist in the establishment of the silver bromide dry plates: first the collodion and albumen types and then the gelatin dry plate of Maddox.

The tanning development of gelatin emulsions by a pyro developer was demonstrated in 1881 by Warnerke.

A considerable advance in the technique of alkaline development came when Berkeley in 1882 improved the pyro developer by the addition of sodium sulphite which prevented the developer solution from quickly turning brown and minimized negative stain.

It is necessary to go back five years to note the discovery of the iron-oxalate developer by Carey-Lea in 1877, and two years to 1880 when Abney published the alkaline hydroquinone developer for gelatin-bromide negatives.

In 1880, too, Eder and Toth showed that pyrocatechin (catechol) would serve as an alkaline developer for dry plates. The next developers to be suggested were hydroxylamine, by Egli and Spiller in 1884, and phenylhydrazine, by Jacobsen in 1885.

The important developer discoveries which were to follow, up to the end of the century, sprang from the great expansion of the German dyestuffs industry. The outstanding figure in developer work at that time was Andresen who, noting the success of the polyhydroxybenzene compounds, turned his attention to analogous amino compounds. He discovered paraphenylenediamine, para-aminophenol and similar compounds as developers in 1888, Eikonogen in 1889, and in 1891 brought para-aminophenol on to the market as a very concentrated developer solution (Rodinal).

Although Andresen had claimed a very wide range of aminophenols within the scope of his patent, it was left to another, Bogisch, to search through the field again and to discover the specially valuable developing properties of the methylamino-phenols.

In 1891, the firm of Hauff, by whom Bogisch was employed, took out patents covering a series of aminophenols and marketed Metol. Later, by arrangement between Hauff and Agfa, to whom the master patent belonged, the same compound was marketed under the name Metol-Andresen.

More recent developing compounds of importance are listed in the table.

Developer Combinations. Of the developing agents available by the last few years of the nineteenth century, some were found to give desirable working qualities when used in pairs.

Chadwick, in 1891, used Eikonogen together with hydroquinone and this combination was sold in tabloid form by Burroughs Wellcome and Co. in 1895.

DATES IN DEVELOPMENT HISTORY

Date	Developing Agent	Inventor
1837	Mercury vapour	Daguerre
1840	Gallic acid	Fox Talbot
1844	Iron sulphate	Hunt
1851	Pyrogallol	Archer, Liebig, Regnault
1880	Hydroquinone	Abney
	Catechol	Eder and Toth
1884	Hydroxylamine	Egli and Spiller
1885	Phenylhydrazine	Jacobsen
1888	Para-phenylenediamine	Andresen
	Para-aminophenol	Andresen
1889	Eikonogen	Andresen
1891	Amidol	Andresen, Bogisch
	Metol	Andresen, Bogisch
	Glycin	Bogisch
	4-aminodiethylaniline	Hauff
1896	Ortho-aminophenol	Hauff
	Ortho-methylaminophenol	Hauff
1899	Chloro-hydroquinone (and bromo-)	Lüppo-Cramer
1904	Ortho-phenylenediamine	Lumière—Seyewetz
1914	4-amino-3 methyl diethylaniline	Fischer
1935	Ascorbic acid (vitamin C)	Mauer—Zapf
1940	Phenidone	Kendall

The metol-hydroquinone combination can be ascribed to no individual inventor but was in use in 1894 and was recommended by the Nepera Chemical Company in 1899 for use with its Velox gaslight paper. Gaslight paper helped to popularize the M.Q. developer.

In 1902, Lumière and Seyewetz patented the crystalline addition product of metol base and hydroquinone and sold it in 1903 as Metoquinone.

Chloranol consisted of metol and chlorohydroquinone and was patented by Lumière and Jugla in 1914.

Paraphenylenediamine together with hydroquinone formed the developing agent Hydramine of Hauff, 1896. Ortol of Hauff, 1896, was composed of hydroquinone with orthomethylaminophenol, and another compound of the same date consisted of catechol and paraphenylenediamine. This last compound was marketed in 1938 as a fine grain developer, Meritol.

In 1935 Agfa introduced the Atomal developer which utilized hydroxyethyl-o-aminophenol and lately this compound together with glycin has formed the basis of Promicrol patented by John and Field.

The latest combined developer is Phenidone-hydroquinone which is based on l-phenyl-3-pyrazolidone discovered as a developer by Kendall in 1940 but not produced commercially until 1951.

Chromogenic Development. Several developing agents such as pyrogallol will produce a

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

coloured dye image together with the silver image and some developers will react with their own oxidation products to give dye images, but none of these has proved of value in colour photography.

In 1913 Fischer found that suitable coupling agents could be added to paraphenylenediamine or para-aminophenol developer solutions to form dyes of the indophenol, indamine, indoaniline, azomethine, and indothiophenol classes. This type of coupling development forms the basis of the modern colour processes, though many systems incorporated the coupler in the emulsion. G.I.P.L.

DEVELOPMENT PAPERS. Contact and enlarging papers coated with an emulsion which forms a latent image on exposure. The latent image is invisible until it is turned into metallic silver by being developed with suitable chemicals. Modern chloride, bromide, and chlorobromide papers are of this type.

See also: *Papers.*

DEVELOPMENT THEORY. Many of the chemical and physical changes that take place in the silver emulsion during processing are still not fully understood. This description gives in the simplest terms possible what appears to happen during development.

Chemical Development. In chemical development the essential function of a developing solution is to convert to metallic silver those silver halide emulsion grains that were partly decomposed by a previous exposure to light. This conversion is achieved by a process of chemical reduction that involves the transfer of electrons from solution into the silver halide grains, e.g.:

$$AgBr + \text{electron} = Ag + Br^-$$

or: silver bromide plus an electron gives metallic silver plus bromide ion.

The electrons required for this reaction are most conveniently obtained from aromatic organic reducing agents of the polyphenol (e.g., hydroquinone), aminophenol (e.g., metol), or polyamine (e.g., paraphenylenediamine) types.

hydroquinone metol (base) paraphenylenediamine (base)

Particularly in the case of the phenolic reducing agents, the liberation of electrons is greatly facilitated by an increase in the alkalinity of the solution which induces the dissociation of the acidic hydroxyl groups. For this reason alkalis such as sodium carbonate, sodium borate, or sodium hydroxide are included in the developer solution. In some cases the emulsion is soaked in developing agent solution in one bath and is then transferred to an alkaline bath.

The addition of sulphite to the solution is necessary to inhibit the reaction of the reducing agent with atmospheric oxygen and to remove the developer oxidation products which would accumulate, retard development and stain.

In tanning developers, where it is the developer oxidation products that harden the gelatin, the sulphite concentration must be kept very low. Since sodium sulphite is itself a mild alkali it is not necessary to add a further alkali if a slow-acting metol developer is required; and amidol-sulphite solutions act quite rapidly at this low level of alkalinity.

The reducing action of the developing agent solution is exerted alike on both the exposed and unexposed grains and, in a sufficiently long time, all would become reduced to silver. The function of the latent image is catalytic; that is, those silver halide grains that carry a latent image are reduced much more rapidly than those that do not. The reduction of non-image grains causes a uniform veil, or fog, to be formed. Some fog can be tolerated in a negative but not in a print or diapositive.

The addition of small quantities of soluble bromide to the developer in many cases retards the reduction of the non-image grains more than that of the grains carrying latent image. The action of the soluble bromide is presumably connected with its ability to diminish the availability of silver ions at the surface of the silver halide grains. In some applications soluble bromide is not so efficacious as certain organic agents such as benzotriazole.

Physical Development. In physical development the enlargement of the latent image specks is achieved by the deposition upon them of silver that is not necessarily derived from the silver halide in the emulsion. A silver salt is added to the developer solution where it is slowly reduced to form a supersaturated silver solution. The presence of the latent image nuclei causes the silver to be deposited from solution, and the latent image specks become virtually silver plated. In time the physical developer will plate silver at random on to the walls of the dish and over the surface of the emulsion.

Since the rôle of the silver halide originally in the emulsion is to provide the latent image material during the exposure, it is not necessary afterwards. For this reason physical development can be effected after the exposed emulsion has been fixed out in a non-acid fixer. Development by the polyamine developers such as paraphenylenediamine is mainly physical because of their solvent action on silver halides.

The degree of apparent uniformity—the graininess of the developed image—depends primarily upon the characteristics of the emulsion used. However, for a given emulsion, the graininess of the image can be affected by

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

the development conditions. In general, slow development to a low gamma yields a less degree of graininess, and the inclusion in the solution of solvents, such as thiocyanate or sulphite in high concentration, is beneficial.

The semi-physical development effected by paraphenylenediamine gives the finest-grained images, but with an effective loss of 70 to 80 per cent of the sensitivity of the emulsion. The metol fine-grain developers strike a compromise between loss of speed and fineness of grain. G.I.P.L.

DEVILLE, E. Dates unknown. Surveyor-general of Canada. Contributed to the theory of the half-tone screen (1895) and to photogrammetric restitution (1902).

DEXTRIN. Constituent of mountants.

Characteristics: Whitish powder.

Solubility: Slightly soluble in cold water, gives a milky solution if dissolved in boiling water. This solidifies on cooling.

DIACTINIC. Transparent to actinic light rays. An obsolete term applied to materials (e.g., filters) which allowed actinic light to pass.

DIAMINOPHENOL HYDROCHLORIDE. Developing agent; amidol. Sometimes also used as the free base, diaminophenol.

DIAPHRAGM

The diameter of a given bundle of light rays passing through a lens determines the brightness of the image formed. The maximum diameter of this bundle depends on the optical diameter of the lens. By placing plates with holes of various sizes, or a set of metal leaves to form an adjustable hole, in the light path of a lens it is possible to adjust the diameter of this bundle of rays, and hence the intensity of illumination of the image. The device with such a hole is known as a diaphragm. A small hole lets through less light than a large one, so the size of the hole can be used to alter the exposure.

Varying the size of this hole has two other effects. The first is that the hole in the diaphragm controls the angle of the cone of rays forming the image.

When the lens is focused sharply on the plate, the image of a point subject is produced by the tip of a cone of light rays coming from the back of the lens. If either the subject or the plate changes its position, the tip of the cone no longer coincides with the surface of the plate and the point image becomes a circular patch. The size of the patch depends on the angle of the cone and how far the tip is displaced behind or in front of the surface plate.

As the size of the hole in the diaphragm is reduced, the angle of the cone of rays becomes narrower and a change in the distance of the subject from the lens, or the lens from the plate produces a smaller change in the diameter of the image patch. So a small hole increases the depth of field covered sharply. And it also increases the range of backward and forward movement of the plate—i.e., the depth of focus—within which the lens will give a sharp image of a particular subject. In other words, focusing is made less critical when the hole in the diaphragm is small.

With cheap lenses the margins of the lens are not as completely corrected for aberrations as the central portion. In this second case, therefore, the diaphragm is so designed that even at its largest opening the diameter of the bundle of light rays passing through does not use the entire lens. Thus the image is formed only by the more highly corrected rays passing through the centre of the lens.

Waterhouse Stops. Early photographic lenses were supplied with sets of separate metal diaphragms which provided a range of hole

DIAPHRAGMS. Top: *Old sliding (Waterhouse) stops carried on a metal plate which is slid into a slot in the lens barrel.* Centre right: *Rotating stop plate.* Centre left: *Iris diaphragm consisting of a set of sliding blades.* Bottom: *Double-blade diaphragm positioned for a large opening* (left) *and a small opening* (right).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

sizes. The diaphragms were called Waterhouse stops after John Waterhouse of Halifax who invented them in 1858. There was a slot in the lens barrel into which the diaphragms were inserted. Each diaphragm had a number referred to as a stop number.

Later Waterhouse stops were replaced by rotating stop plates. Since *c.* 1900 the iris diaphragm with variable apertures has been in general use, but the practice of referring to particular diaphragm openings as stops has persisted.

Process lenses still have, in addition to their iris diaphragm, a slot for Waterhouse stops, which often do not have circular openings because the shape of the aperture has an effect upon the dot formation produced by engraved half-tone screens.

Simple Diaphragms. The earliest type of diaphragm was simply a single hole in a plate that could be inserted between the lens components through a slit in the barrel of the lens mount—i.e., the Waterhouse stop. This idea was soon dropped because it meant that the photographer had to carry around a number of separate plates each drilled with a hole of a different size to give him a range of stops.

An improvement on this simple system is the stop plate carrying a number of holes arranged so that they can be brought into position by rotating or sliding the plate. This method is cheap and effective; it is still used on many inexpensive cameras.

Iris Diaphragm. Apart from the simpler cameras the type of adjustable stop now used almost universally for controlling the lens aperture is the iris diaphragm. The hole in this type is formed by a set of thin metal blades, mounted on a ring around the lens. Movement of a control lever on the outside of the lens mount closes the blades inwards or opens them out to make the hole smaller or larger. The *f*-number of the aperture is indicated on a scale alongside the control.

The greater the number of blades in an iris diaphragm, the more nearly the hole approaches a perfectly circular shape. At the same time, a truly circular hole is by no means essential for everyday photography.

In practice, the number of leaves in the diaphragm of the average camera lens covering the popular $2\frac{1}{4} \times 2\frac{1}{4}$ ins. format is ten.

This type of diaphragm is sometimes responsible for a peculiar form of highlight distortion. Bright points of light—e.g., stars in an astronomical telescope—appear as star-shaped patches. The number of points is related to the number of leaves in the diaphragm.

The iris diaphragm is generally an integral part of the lens/shutter assembly. Diaphragms are also used for controlling the amount of light passed by other optical systems—e.g., on the substage condenser of a microscope.

Double Blade Diaphragms. Another method of controlling the size of the lens opening is by the use of two movable diaphragm plates, each carrying a curved slot of decreasing width. The slots in the two plates overlap in the lens axis. Movement of the two plates brings either the broad end or the narrow end, or any intermediate position, of the slots to overlap in the centre of the lens, thus forming openings of different sizes. The shape of the opening usually also varies from approximately round at the largest aperture to more or less square at the smallest.

This type of diaphragm is used on inexpensive still and especially cine cameras, and also on cameras with automatic exposure control. There the movement of the diaphragm blades is controlled by coils energized by the current from an exposure meter cell.

Position of Diaphragm. In a lens which has only one element, the diaphragm may be placed in front or behind. The position affects the distortion of the image: if in front, it tends to produce barrel distortion and behind, pincushion distortion. It is generally placed in front of simple lenses.

In lens with several components, the diaphragm is almost always placed between two of the components—e.g., a symmetrical lens has the diaphragm inserted midway between each of the identical elements.

Effective Stop Diameter. The important thing about a stop is not its real diameter, but the diameter of the beam of light that it allows to pass through the lens to make the exposure. If the diaphragm is in front of the lens, then the two figures are the same—i.e., the diameter of the incident beam of light is equal to the diameter of the aperture in the diaphragm.

Where the diaphragm is placed between the lens components, the light incident on the front of the lens converges before it reaches the aperture. So in this case the diameter of the incident beam is greater than the diameter of the aperture through which it has to pass.

The diameter of the incident beam that just fills the aperture is known as the effective diameter of the diaphragm aperture, and the area of the beam is the effective aperture. In modern anastigmat lenses it may be 30 per cent greater than the actual diaphragm aperture.

The effective diameter of the diaphragm cannot be measured directly. It is measured in this way: the lens is focused on infinity and a sheet of opaque paper is substituted for the focusing screen; a pinhole is made in the paper opposite the centre of the lens; a sheet of sensitized paper is held in contact with the front of the lens, emulsion inwards; a bright light is held against the pinhole long enough to produce a black disc on the paper after development. The diameter of this exposed disc is the effective diameter of the stop.

Effects of Stopping Down. Apart from controlling the amount of light passing through the lens and governing the depth of field, changing the lens stop has several other effects.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

EFFECT OF LENS STOP. Top: *With simple lenses stopping down may change plane of sharpest focus by cutting out the uncorrected marginal rays.* Centre: *At smaller apertures the angle of the cone of rays is reduced, increasing the available depth of field.* Bottom: *The effective diameter of the stop depends on its position. In front of the lens it is identical with its actual diameter; behind, its effective diameter is larger.*

With both cheap lenses, and also many of better quality, stopping down may improve definition. This is because the correction of the lens for central rays is usually higher than for marginal rays. Stopping down there cuts out some of the marginal rays, leading to better image quality.

With modern high-speed lenses the correction is a compromise taking in both central and marginal rays. A certain amount of stopping down will still improve definition, but beyond the point of optimum definition no improvement is gained—in fact the image quality may deteriorate because the balance of correction between central and marginal rays may be upset.

Secondly, this change in balance between central and marginal corrections may also shift the plane of sharpest focus. The lens then in effect behaves as if it changed focal length during stopping down.

Thirdly, at very small openings the image definition deteriorates owing to diffraction. Light waves are slightly bent very near the edge of the diaphragm opening, leading to a certain amount of light scatter and unsharpness. At a small lens opening these deviated rays form a significant proportion of the light rays passing through the diaphragm and hence impair image sharpness.

Finally, a small diaphragm opening may improve the evenness of illumination in the image plane. This is likely to be the case where the lens mount itself tends to cut off some light (by vignetting). At a smaller diaphragm opening the reduced cone of light is no longer obstructed by parts of the lens mount and the effect of vignetting disappears. (Some falling off in illumination from the centre to the edges of the image always occurs. This is partly due to the longer path of oblique light rays from the lens to the image plane, and partly to the fact that the diaphragm opening as seen from any point near the edge of the image appears distorted—e.g., from round to oval.)

Relative Aperture. The effective diameter of the stop decides the amount of light that can pass through the lens to form an image. But the same amount of light can be spread over either a small brilliant image (with a lens of short focal length) or a large weak image (with a lens of long focal length).

So the important thing in deciding the brilliance of the image is not simply the size of the effective aperture. It is its size in relation to the focal length of the lens that matters. For this reason, the size of the aperture is always given as a fraction of the focal length—i.e., F/D where F is the focal length of the lens and D the effective diameter of the aperture. This fraction is called the relative aperture of the lens. All lenses with the same relative aperture in theory form images of equal brilliance of the same subject.

For example, a lens of focal length 12 ins. and an effective aperture of $1\frac{1}{2}$ in. diameter would have a relative aperture of 8—i.e., $12/1\frac{1}{2}$. Similarly a lens of focal length 6 ins. and an effective aperture of $\frac{3}{4}$ in. would also have a relative aperture of 8—i.e., $6/\frac{3}{4}$. So both lenses would give an image of equal brilliance of the same subject, and call for the same exposure.

The convenience of this method of stating the size of the stop is obvious. It means that the photographer has no need to know the actual diameter of the stop when he is adjusting his exposure; whether his camera is a 35 mm. miniature or a 8 × 10 ins. field camera, the same relative aperture number will give him the same exposure.

***f*-numbers.** The number indicating the relative aperture given by a particular stop is called the *f*-number, and its value is expressed by the letter *f* followed by the figure—e.g., *f* 4·5 which indicates that the effective diameter of the stop goes into the focal length of the lens 4·5 times. All lenses with the same *f*-number require equal exposures, no matter what the focal length of the lens or the diameter of the aperture may be. As the aperture increases, the *f*-number gets smaller; a big *f*-number—e.g., *f* 64—indicates a small aperture and a small *f*-number—e.g., *f* 2·0—indicates a large aperture. Where the lens has an adjustable diaphragm, the *f*-numbers are calculated for a number of stop sizes covering the whole range

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

of the aperture adjustment. These are engraved on a scale alongside the diaphragm control.

Aperture Scales. The intensity of the light forming the image at any particular aperture (and hence the exposure) varies directly with the area of the aperture—i.e., with the square of its diameter D since

$$\text{Area} = \frac{\pi}{4} \times (\text{Diameter})^2$$

This is to say that it varies with

$$\left(\frac{1}{f\text{-number}}\right)^2$$

because the diameter of the stop

$$D = \frac{1}{f\text{-number} \times F}$$

(where F = focal length of lens)

So if the exposure is known for one aperture, it is possible to calculate the exposure given by any other by comparing the inverse squares of the *f*-numbers—i.e., the exposures at *f*-numbers, *f* x and *f* y will vary in the proportion

$$\frac{1}{(f\,x)^2} : \frac{1}{(f\,y)^2}$$

In other words, the exposure given at *f* 11 is half the exposure given at *f* 7·7 since $1/(11)^2$ is half $1/(7{\cdot}7)^2$.

It would be possible to choose any scale of *f*-numbers and work out the effect of changing from one to another by comparing the squares in this way. In practice the thing is made much easier by choosing the steps on the aperture scale so that a step up or down doubles or halves the exposure. So a scale starting with a maximum aperture of *f* x, would run: *f* x; $\sqrt{2}\,f$ x; 2 *f* x; $2\sqrt{2}\,f$ x, etc.—giving relative exposures of 1 : ½ : ¼ : ⅛, etc.

The actual values on such a scale vary according to the starting point chosen, so it is possible to have any number of scales all based on progressive doubling of the exposure.

U.S. System. At first, practically every lens maker marked his diaphragms according to his own scale, but in 1881 the Royal Photographic Society proposed a Uniform System (hence U.S.) based on what was then the largest lens aperture; *f* 4. So the scale ran: *f* 4·0, *f* 5·6, *f* 8, *f* 11·3, etc. The Society recommended that each stop should be known by its relative exposure value, giving a scale of U.S. numbers: 1 (= *f* 4), 2 (= *f* 5·6), 3 (= *f* 8), 4 (= *f* 11·3), etc.

This system of marking was not much used in Britain or on the Continent, but it was used in America, particularly on the earlier Kodak cameras. It is being used again now for enlarger lenses where relative exposures are more important than actual aperture values.

Current Scales. Today all diaphragms are marked in *f*-numbers, but there are still three scales in existence since different lens manufacturers have based their scales on different maximum apertures.

In each case however the steps are chosen so that a change from one number to the next higher halves the image brightness and calls for twice the exposure.

The three current scales of *f*-numbers are shown in the table below. In some cases, where different manufacturers give slightly different figures, the less common is given in brackets below the usual figure.

Opposite each figure is shown the light-passing power of the aperture in relation to a standard of 10,000 units passed by an aperture of *f* 1.

British lens manufacturers mostly use the international series, 2, 2·8, 4, 5·6, 8, 11, 16, etc. which was adopted as the official British Standard in 1949, and which is now used throughout the world. European lens manufacturers at one time used to prefer the scale series, 2·3, 3·2, 4·5, 6·3, 9, 12·5, 18, etc.

Stops in this now obsolete Continental series pass about one-third less light than the nearest corresponding numbers on the British scale, but for all practical purposes the difference can be neglected. Often, in fact, a lens which has a full aperture that does not correspond to the

APERTURE SCALES COMPARED

maker's normal scale may have one or more of the larger apertures numbered in the other series—e.g., 4·5, 5·6, 8, 11, 16.

T-Stops. Some of the light that would otherwise pass through the lens to form the image is always lost by reflection at the surfaces of the lens components. Coating the lens reduces this loss, but does not get rid of it altogether.

One lens manufacturer calibrates the stops in terms of the actual measured or calculated light transmission. The *f*-numbers thus obtained are called T (transmission)-stops. T-stops are always slightly higher than the corresponding *f*-number.

The system has been adopted principally for professional cine cameras. It is doubtful whether it has any real advantages for normal still photography. This is because most of the light supposedly lost by reflection does actually appear as general fog on the negative, so that it must in any case be taken into account as contributing to the exposure. On the other hand, the relative aperture may be incorrect from the light-gathering point of view for other reasons: the actual focal length may differ from the nominal value and the effective aperture may be different from the theoretical value. T-stop marking takes care of all these points. There is a further point that the theoretical *f*-number must be used in calculations of depth of field and hyperfocal distance which are based on the geometry of the lens and not on its actual light transmission. In practice, however, the differences in depth of field values derived from T-stops and from *f*-numbers are negligible.

Coupled Diaphragms. On some shutter and diaphragm assemblies, the diaphragm control is coupled to the shutter speed control in such a way that a change in the setting of one automatically changes the other to keep the resulting exposure the same. The coupling itself is adjustable so that the relationship between stop and shutter speed can be set to give any total value of exposure (known as the exposure value).

The idea is taken further in cameras coupled with a built-in exposure meter. The meter is pointed at the subject and the indicator needle is made to coincide with a reference mark. The control which does this automatically sets the diaphragm-shutter coupling ring to give the correct range of stop-speed values required for the prevailing light conditions. At that point it is still open to the photographer to select a particular shutter speed or stop (but not both) to serve his purpose.

In the so-called programmed shutter the diaphragm adjustment is linked with the shutter speed control, in such a way that adjustment yields a series of exposure value settings by progressively closing down the lens aperture and speeding up the shutter. This system does not provide alternative aperture-speed combinations for the same given exposure or exposure value. Some programmed shutters achieve this result by dispensing with a separate lens diaphragm altogether, and controlling the degree as well as the time of the opening of the shutter blades. Programmed shutters may or may not be coupled with an exposure meter system.

Automatic Exposure Control. On modern automatic or electric eye cameras the diaphragm adjustment is directly or indirectly controlled by an exposure meter—without even the need for making a meter needle coincide with any setting mark. In its simplest form—as used in a few cheap still and many cine cameras—the current from the exposure meter cell is used to move the blades of a double blade diaphragm to yield different openings.

More advanced electric eye systems, mainly on still cameras, employ a mechanical cam system which scans the position of the exposure meter needle. The cam in turn controls a spring drive that automatically closes down (or opens up) the lens diaphragm to an aperture corresponding to correct exposure. This takes place immediately before the shutter is released.

In more complex systems, especially in professional motion picture cameras, the photo cell may be used to control a motor driven diaphragm adjustment.

Automatic Diaphragm Control. Apart from meter-controlled diaphragm systems, pre-selector diaphragms are also used in single-lens reflex cameras. There the subject is first focused on a screen at the full aperture to get a bright image, and the exposure is made at the smaller aperture. The automatic mechanism here ensures that the diaphragm closes down to a pre-selected value (which may or may not be set by an exposure meter) just before the exposure. There are systems of varying complexity and automation for this purpose.

The simplest form is the straightforward manual pre-set diaphragm. The controls consist of the normal diaphragm setting ring and a second ring incorporating a mechanical stop and carrying the aperture scale (or setting index). During focusing the diaphragm ring is turned to its position for full aperture, while the selected working aperture is set on the second ring. Immediately before the exposure, turning the diaphragm ring as far as it will go sets the lens to the pre-selected stop. After the exposure the diaphragm ring is turned back again to the full lens opening.

Semi-automatic pre-selector systems are similar, again incorporating a second ring that controls a mechanical limit stop. The diaphragm ring is however in this case spring-driven and held tensioned at full aperture. On pressing the shutter release, a suitable linkage releases the spring, thus closing down the diaphragm to the pre-selected limit, an instant before the shutter opens. After every exposure the pre-selector mechanism needs retensioning by hand, which at the same time brings the diaphragm back to its full opening.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Fully automatic pre-selector diaphragms require no separate retensioning. The tensioning mechanism is often linked with the film transport (and shutter tensioning) so that working the transport movement brings all parts of the camera back to readiness for the next exposure. On reflex cameras where the mirror springs back after the exposure, the diaphragm may at the same time open again to full aperture as well.

Most of these forms of automatic diaphragm control are also available on reflex cameras with interchangeable lenses. This involves linking the automatic diaphragm release with the shutter release on the camera. Modern reflex cameras achieve this with an internal lever inside the lens mounting ring on the camera, arranged to engage a suitable control at the rear of the lens itself. Alternatively, the lens may carry its own release button to actuate the semi-automatic or automatic diaphragm. When the lens is mounted on the camera this button also bears on the camera release button to make the exposure an instant after the lens diaphragm has jumped to its pre-selected value. DIAPOSITIVE. Positive picture on a transparent support intended for viewing by transmitted light—e.g., lantern slides and transparencies.

DIASCOPE. Optical projector for showing enlarged screen images of transparencies or diapositives.

DIATHERMIC MIRROR. Mirror with a coating that reflects visible light but transmits infra-red and heat rays. Used in light fittings and projector optical systems requiring a high concentration of light, where the heat also produced by the light source needs eliminating as far as possible.

See also *Heat filter; Mirror.*

DIAZO PROCESSES. Reproduction process in which a diazonium salt is destroyed by exposure to ultra-violet, violet or blue light. Materials using this system are also known as dyeline materials. An orginal document having a light-absorbing image (printing ink, pencil, Indian ink, aniline dye) is placed in contact with the dyeline material and the sandwich is exposed with the original facing a source of suitable light. The radiation is absorbed by the image but is transmitted by the non-image areas on to the diazonium salt in the surface of the underlying dyeline material. Exposure is continued until the diazonium salt is just completely bleached. When the sandwich is separated the dyeline material shows a positive copy of the original in unbleached diazonium salt. This is, of course, still light-sensitive and is pale yellow in colour. The diazo image is transformed into a coloured, visible, stable azo dye image by treatment with a suitable phenolic coupler. This step is usually termed development.

Because the dyeline process lacks the amplification stage of latent-image catalyzed reduction of silver halide that characterizes silver-based photography, the exposure times are relatively long and dyeline products are unsuitable for camera exposures. On the other hand, the low sensitivity allows handling in normal room lighting. Exposure to strong daylight, and especially sunlight, should be avoided. Special dyeline materials are made that are sufficiently sensitive to be exposed to a projected image, so long as an intense light source is used and the optics have a high ultra-violet transmission.

Applications. Diazo and dyeline products find their widest use in the direct copying of documents on a translucent base, such as engineering drawings on tracing paper, linen or matt-surfaced plastic film. In this application it is usual to adjust the exposure so that a trace of diazonium salt is left unbleached in the non-image areas. Development then gives a print having a line image on a weakly tinted background. This procedure ensures that no fine detail in the original drawing is lost by over-exposure.

Another field of increasing exploitation of dyeline copying is in commercial offices, both for convenience copying of correspondence and for systems of accounting, book-keeping, etc., whereby diazo reproduction is taking the place of expensive manual retyping. For this reason many business firms are ensuring that all stationery used has good translucency. Modern high-speed dyeline printing machines use 3–5 kilowatt high-pressure mercury vapour lamps. Alternatively a bank of actinic fluorescent tubes is arranged along the axis of a revolving glass cylinder against which the original and dyeline paper are held in close contact by moving fabric bands. The length of the exposure is adjusted by varying the rate of rotation of the cylinder. Many machines also incorporate a development section so that the paper can be exposed and processed to the final print at speeds of 50 feet per minute or more.

Materials. Two main classes of dyeline products are currently produced. The first is known as the two-component, dry or ammonia type, and the second as the one-component, semi-dry type.

The ammonia papers were the first to be produced commercially and were introduced by Kalle in 1923, being based on the ideas of Kögel. The essential components are a diazonium salt and coupler, both of low coupling

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

power, that will couple only at high pH: an organic acid is added to the coating formulation to prevent premature coupling. Typical diazonium salts, often used as the zinc chloride double salts, are those derived from p-aminodiphenylamine, p-aminodimethylaniline, 2-amino-1-naphthol-5-sulphonic acid and p-aminophenylmorpholine, and couplers are 2,3-dihydroxynaphthalene-6-sulphonic acid, resorcinol and 2-hydroxynaphthalene-3,6-disulphonic acid. Development is effected by treating with warm, moist ammonia fumes.

The one-component or semi-dry products were put on the market by van der Grinten in 1927. The paper is coated with a diazonium salt and development consists of treating the surface after exposure with a thin layer of a solution of a phenol. Modern processing machines use special grooved rollers that will apply uniformly as little as 9 grams per sq. metre developer to the front and 7 grams to the back of the paper, which can therefore be quickly dried by brief passage through a heated zone. The diazonium salts frequently used cover a wide range of coupling activity. At one extreme is 4-N-benzyl-N-ethylphenyl diazonium zinc-chloride, that couples well only under alkaline conditions.

In practice a product coated with this diazo is developed by an alkaline solution of a phenol, borates being very commonly used. Other diazonium salts will couple under neutral or slightly acid conditions (pH below 4·5) and products sensitized with such diazos are developed by solutions containing large quantities of the sodium salts of weak acids such as citric, benzoic or formic. Diazos of this latter class are 2,5-diethoxy-4-phenylacetamidophenyl diazonium zinc-chloride, and 2,5-dimethoxy-4-p-tolylthiophenyldiazonium chloride. Phloroglucinol is almost universally used as the coupler, since it reacts readily with diazonium salts to give dark, almost black, dye mixtures. The acid developers are more resistant to discoloration due to aerial oxidation.

A special class of dyeline products is designed to produce prints that can themselves be used as masters for subsequent dyeline reproduction. These "intermediate" prints take the place of a valuable original drawing. The base for the dyeline coating is either translucent paper, or for special purposes, transparent linen or plastic film. Polyester film is gaining favour for its toughness and dimensional stability. The diazo and coupler are chosen to produce an image that will be acceptable visually but have a high absorption for U.V. and short-wavelength visible light. Resorcinol and its derivatives are frequently used for this purpose, as brown images are produced.

The diazo reproduction process is by nature one of fairly high contrast, so that reproduction of half-tone images is poor. Good reproduction on the usual type of paper, preferably baryta coated, is obtained if a screened positive is used as the original. Special products have, however,

SCREENED DIAZO PRINTING. Diazo screen material carries a strippable screen layer in contact with the diazo layer. The plastic film support acts as a spacer between the original and the diazo layer. Light going through the screen is diffused and reflected back into the diazo layer from light areas of the original; dark areas reflect less or no light, so that in those parts the screen pattern is obtained after processing as a positive half-tone image. A, strippable screen layer. B, diazo layer. C, plastic film support. D, original (image shown shaded).

been developed for half-tone reproduction, but this is an unimportant use.

Preservation of Materials. Diazonium salts have a limited thermal stability, particularly in the presence of moisture, and the manufacturer ensures that the coated paper is produced as dry as possible, and that it is packed in moisture-proof wrapping. Nevertheless, some decomposition slowly occurs, and the practical life is 6–12 months. Storage in a refrigerator considerably extends the life. Opened packets deteriorate much faster. The most obvious change on keeping is a discoloration of the background and stale paper becomes unusable for this reason long before all the diazonium salt has become decomposed.

A recent development has been the introduction of dyeline papers of a truly dry nature. These are developed by heat after light exposure. Fundamentally, these thermal diazo papers are two-component ones in which the alkali for development is obtained by the action of heat, e.g. the decomposition of a chemical, such as the formation of ammonia from urea. The main difficulty is to produce a material that will give an intense image and have a reasonable shelf life.

Screens. Dyeline products normally give only copies of low contrast by reflex exposure, since most of the light is absorbed by the diazo (with consequent bleaching) before it can be selectively reflected by the non-image areas in the original. If, however, a fine carbon black screen is placed between the diazo and the light, the diazo beneath the dark elements of the screen is protected and is bleached only by light reflected and scattered in the non-image areas. No light is reflected by the image and the diazo remains unbleached in the image areas. Reflex copies of high contrast can therefore be obtained. The screen can be an integral part of the dyeline product, and is stripped away after exposure before development.

Scattering Images. Not typically a dyeline process, but one nevertheless utilizing a diazonium salt, is that of scattering photography. During bleaching by light a diazonium salt

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

forms nitrogen gas as one of the decomposition products. The material for scattering images is a thermoplastic film containing a diazonium salt. On exposure, the nitrogen from the diazo forms micro-bubbles at high pressure. When, shortly after exposure, the film is heated the plastic softens and allows the nitrogen bubbles to expand. At the same time some crystallization of the polymer occurs and the result is a multi-cellular structure of 0·5–2·5 A. unit cell, which is highly light-scattering. Such an image will be equivalent to a density of at least 1·0 when inserted in the image plane of a projection system. The process gives a negative from a positive and vice-versa, and is used for making positives from silver microfilm negatives that can be projected on to highly-sensitive dyeline paper for positive prints. The image is fixed by exposure and heating to only a moderate temperature, so that the nitrogen diffuses out without distorting the polymer. D.J.F.

3:5-DICHLORO-2-AMINO-PYRIDINE. Developer improver.

Formula and molecular weight; $C_5H_2N(Cl)_2NH_2$: 163.

Characteristic: White powder.

Solubility: Fairly soluble in water.

DICHROIC FOG. Kind of "bloom", sometimes seen on negatives, which looks purplish by transmitted light and greenish by reflected light. It is more obvious in the shadows than the highlights, and although there are many causes, the effect is always due to a deposit of colloidal silver.

The deposit can generally be wiped off the negative while wet, but once it dries on it may be stubborn. Brief treatment with Farmer's reducer will sometimes remove the fog, or it will generally yield to a bath in the following solution:

Thiourea	28 grains	1·4 grams
Citric acid	28 grains	1·4 grams
Water to make	5 ounces	125 c.cm.

Dichroic fog may be caused by excess of sulphite in a fine-grain developer; by hypo contamination of the developer; by traces of developer in the fixing bath or by insufficient fixing.

DICKSON, WILLIAM KENNEDY LAURIE, 1860–1935. Scottish inventor, born in France. Was Edison's principal assistant in the development of the "optical phonograph" (1888), the Kinephonograph (1889), the Kinetoscope and Kinetograph (1891). Dickson made the first films for Edison. He left Edison in 1894 and joined Latham, with whom he developed the Panopticon in 1895. Left Latham and designed the Mutoscope.

DIETHYL-PARA-PHENYLENEDIAMINE HYDROCHLORIDE. Para-(diethylamino)-aniline hydrochloride. Developing agent for direct colour development with colour couplers.

Formula and molecular weight: $(C_2H_5)_2NC_6H_4NH_2HCl$; 200·5.

Characteristics: Whitish powder.

Solubility: Fairly soluble in water.

DIFFRACTION. Bending of light rays around opaque objects, specially apparent if the opaque object has a sharp edge.

It is customary to consider light as proceeding in straight lines, termed rectilinear propogation, and thus expect it to generate sharp shadows. However close examination of the shadow of an opaque edge illuminated by a plane wavefront shows that there is light present in the shadow which has seemingly been diverted around the edge. This spreading of light at the edge of obstacles is termed diffraction.

This phenomenon may be explained if the light propogation is considered as a wave motion. Each portion of the wavefront acts as a secondary source emitting a spherical wave and a new wavefront is formed as the common tangent to the spherical waves in the direction of propagation. When a wavefront meets an opaque edge the portion of the wavefront passing past the obstruction will spread behind due to the secondary spherical waves just inside the edge.

An example is an image-forming system with a finite aperture. The wavefront in the exit-pupil of a perfect lens imaging a point source will be a spherical wavefront with a sharply defined circular periphery. Due to this limitation of the wavefront the image of the point source is not an exact point but a diffraction disc of light, known as the Airy disc.

It is this disc of light (the actual image of a point source) that limits the resolving power of the optical system. If two object points are so closely spaced that the centres of their images are separated by the radius of the Airy disc then the two images will not be resolvable. For an

DIFFRACTION. When a wave front meets a knife edge, it generates a new wave front at the edge itself. This spreads round the obstacle, leading to some light being apparently bent round the edge.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

optical system with a circular aperture limited only by diffraction the radius of the Airy disc is 0·61 times the mean wavelength of the image forming light divided by the numerical aperture. The resolving power, usually quoted in terms of lines per inch, is the reciprocal of the radius of the Airy disc.

For most photographic purposes it is agreed that the disc of confusion should be restricted to 1/2000 of the focal length of the taking lens if the picture is to be sharp in definition when viewed at the distance which gives correct perspective. For a lens of 2 ins. focal length this is a disc of confusion of 1/1000 in. diameter and the diameter of the Airy disc for a solely diffraction-limited lens will be of the same value when the stop number is 22. For higher stop numbers the Airy disc will increase in diameter proportionately and the image will no longer be satisfactory.

Depending on the state of correction of the taking lens it is possible that the above F/2000 condition is not satisfied unless the lens is stopped down by one or two stops from full aperture. For all stops between this satisfactory value and the stop when diffraction begins to predominate, the lens imagery will be satisfactory.

Where the standard of definition required is higher, the limiting aperture for acceptable freedom from diffraction becomes larger. For certain special purposes it may therefore be desirable not to stop down the lens beyond, say, *f* 11.

A slit aperture placed in an optical system will also give a diffraction pattern whose width is inversely proportional to the slit width and directly proportional to the wavelength of the light. This suggests the use of many slits ruled on a glass plate to separate light of different wavelengths, such a plate being termed a diffraction grating.

The fine periodic nature of woven materials gives similar effects, an example being the star-like patterns seen through an umbrella or a net curtain material. These diffraction patterns have cross shaped structures due to the threads of the material being in perpendicular directions.

DIFFRACTION GRATING. Device for separating out the individual colours in a beam of light of mixed composition. It consists of a set of fine parallel lines ruled on a surface so as to form a grating of alternate, regularly spaced black and white (or transparent) lines, a thousand or more to the inch. When light falls on such a grating, the greater part passes straight through the spaces, but a certain proportion is bent by the phenomenon known as diffraction. The red rays are bent most and the violet least, which is the reverse of the action of a prism. But where the prism spreads out the violet and blue rays more than the red, the diffraction grating spreads the various frequencies evenly throughout the spectrum.

For most work—e.g., spectroscopy—a diffraction grating is better than a prism. At the same time, the spectrum given by a diffraction grating is less intense than one given by a prism because most of the light passes through the grating without being affected. Moreover, the prism forms one spectrum while the grating forms a series of spectra.

There are two sorts of diffraction grating; one consists of opaque lines ruled on glass (called a transmission grating) and the other consists of lines ruled on a metal surface (reflection grating). The spectrum of the first is seen by transmitted light, and the second by reflected light.

DIFFUSER. Any light-scattering medium placed in the path of a beam of light to soften its character. Undiffused light as it radiates from a light source is sometimes unsuitable for many types of photograph—e.g., portraiture, figure studies, still life—because it casts sharply defined shadows. While a hard light is excellent for emphasizing surface texture, roundness and subtleties of modelling call for a soft light which shifts the emphasis from the finer details to the broader conceptions of shape and form.

There are several ways of diffusing a light. The commonest is to furnish the lamp with a satin-finish or matt white reflector in place of a polished reflector, or to use no reflector at all. Reflections from matt surfaces are sufficiently diffused to avoid really sharp shadows.

Where even more diffusion is required or where the area of the reflector is small in relation to the source—e.g., in a spotlight—a diffusing screen is placed in front of the light. This screen may consist of a disc of fine white fabric or opal glass fastened over the opening of the lamp reflector, or a large screen of similar material supported on a stand between the lamp and the subject.

Flash-bulb reflectors are often fitted with a translucent plastic screen which serves the double purpose of diffuser and a protective shield if a flash bulb should explode on firing.

Diffusers may also be used over the camera or enlarging lens to soften the over-all definition of the picture. Diffusers of this type are usually clear glass inscribed with concentric circles, but very thin black chiffon or similar fabrics can be used quite effectively.

See also: *Lighting the subject; Soft focus; Texture screens.*

DIFFUSION. When light rays are reflected off or transmitted through a material in all directions, they are said to be diffused. White paint is a good diffuser because the light is reflected from a large number of microscopic flakes of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

DIFFUSION. Top: Light reflected from a rough surface is diffused by reflection in every possible direction. Bottom: Light passing through a translucent medium is diffused by scattering, yielding an evenly illuminated surface

pigment, all lying in different directions, and therefore spreading rays at random. Milk is a good diffuser because it consists of large numbers of suspended globules of fat which behave in the same way as the flakes of pigment in the white paint.

Coloured materials will also diffuse light, but the fact that they appear coloured means that some of the light has been absorbed. So they are not as efficient in diffusing as white materials.

Soft focus lenses and diffusing discs may be used for either taking or enlarging photographs (or both) to diffuse and soften the image where extreme sharpness is undesirable. This effect is not really diffusion so much as refraction. What happens is that part of the light is used to produce a sharp normal image, and part is distorted by a refractive effect to produce one or more overlapping images. The combined effect is a softened but basically sharp image.

Opalescent diffusing screens are true diffusers and tend to spread light sources evenly and soften the sharpness of shadows.

DIFFUSION ATTACHMENT. Disc of lightly engraved or etched glass or transparent plastic. They are made to fit in front of the lens of a camera or enlarger to blur part of the image-forming rays and soften the definition of the picture. Chiffon and similar fabrics can also be used in the same way.

See also: *Soft focus.*

DIFFUSION TRANSFER

Photographic process in which a negative image is developed in contact with a suitable receiving layer, so that the unused silver salts diffuse into this layer, forming there a positive. The latter is then stripped off the negative which is usually discarded.

The process was invented almost simultaneously in 1939 by A. Rott of Gevaert and E. Weyde of Agfa. Intended initially as a method of rapid document copying, diffusion transfer systems have come to be applied also in instant-picture cameras.

Chemistry. The negative material for the diffusion transfer process consists of a normal sensitized silver halide layer containing also developer chemicals. The positive material is not light sensitive, contains development nuclei (which render unexposed silver halide or silver halide complexes developable) and a silver halide solvent such as sodium thiosulphate. The developer is usually an alkali solution, which may however also contain silver halide solvent. The primary role of this solution is to activate the developer in the negative layer.

During development the negative and the positive sheets are in close contact. The developer develops the negative image in the usual way. At the same time the unused silver halide in the negative layer is rendered soluble and diffuses into the positive layer. Under the influence of the development nuclei it is there reduced to metallic silver, forming a positive corresponding to the negative image. After development the two layers are peeled apart. Usually the negative is discarded, but can in certain cases be re-used for repeated transfers.

Photo-copying. During the transfer process the image is reversed left to right. To obtain a right-reading positive the negative must therefore be laterally reversed, which is the case with reflex printing and with contact printing through the back of a translucent original. The latter procedure usually loses some definition; hence reflex printing is the commonest method with diffusion transfer copying. Accordingly the contrast of the negative material must be very high, and this method is suitable only for copying line originals. Continuous tone originals need screening through a contact screen, which is at the best a make-shift procedure owing to the loss of definition and gradation.

The steps for making a diffusion-transfer copy are:—

(1) Place the negative paper face up on the top of a contact printing box and place the original on top of the negative.

(2) Expose for the appropriate time through the back of the negative paper.

(3) Feed the negative and a positive sheet into the developing solution. Mechanized developing machines enable the two sheets to be fed in, face to face, simultaneously, but separately. After passage through the solution—which soaks both layers—a pair of rollers squeegees the two papers into intimate contact.

(4) About half to one minute after the sandwich emerges from the processing machine, the negative and positive can be stripped apart.

Positive papers are also available coated on both sides, for producing double-sided copies.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

THE DIFFUSION TRANSFER PROCESS. 1. A negative paper N is placed in contact with the original O and exposed by the reflex method through the back of the negative paper. Light reflected from the white parts of the original produce a developable image in the negative layer. 2. The negative image developes in the developer D. 3. The developer-soaked negative is brought into intimate contact with a positive paper P. This is not sensitive to light, but contains special chemicals. These reduce unexposed silver salts diffusing into the positive from the negative. 4. The result is a positive image which can then be separated from the negative.

In this case a negative paper is exposed from each side of a double-sided original, and the two negative sheets fed through the processing machine together with the double-sided positive paper in between them.

Some types of diffusion transfer photocopying paper permit the production of several prints from one negative. In this case the negative paper is fed repeatedly through the developer, each time with a new positive sheet. Negative papers for this purpose have a higher silver halide content, leaving more halide available for diffusion, while the corresponding positive papers have fewer development centres. The positives obtained are usually grey rather than black, and about 8 to 10 positives can be produced from one negative.

High-speed negative papers for transfer diffusion copying can be printed by projection. In this case the original (for example a microfilm transparency or negative) must be placed in the enlarger reversed left-to-right to compensate for the lateral reversal taking place during transfer.

A special material for projection printing has the negative layer (sensitized) coated on top of the positive receiving layer. The negative layer in this case is a soft water-soluble gelatine layer. During processing the positive image is formed in the usual way in the lower non-sensitized layer, after which the top layer with the negative image can be washed off by treatment in warm water. With this material there is no need for lateral reversal of the projected image.

For offset litho use special positive sheets are available, with the receiving layer coated on aluminium. After normal printing and development this yields an offset litho master for direct use on small office offset machines.

Camera materials. The diffusion transfer principle is also used for photography in the camera, the best known (and first) system being that of the Polaroid Land camera. This takes the negative and the positive material in separate rolls or stacks of connected sheets. The negative is exposed in the image plane of the camera. The activating reagent for the developer (incorporated in the negative emulsion) is contained in small pods or capsules. The solution contains a jellifying agent to permit spreading between the negative and positive layers, without excessive contamination of the camera itself. After the exposure pulling a paper tab or leader draws the negative and positive between two steel rollers in the camera. This breaks the pod containing the activating chemicals and spreads them between the two sheets. After the appropriate processing time (from 10 seconds to 2 minutes, according to the type of material) the positive can be peeled off the negative.

Black-and-white print materials for the Polaroid Land camera use negative and positive papers; the effective emulsion speed may range from 200 up to 3,200 A.S.A. Special materials of this kind are available for oscillograph recording with speeds up to 10,000 A.S.A.

Alternative materials include a positive layer coated on film base for transparencies, and a negative coated on film base for subsequent recovery of the negative. After fixing and washing this film negative is then suitable for handling like any other normal negative, including for making enlargements.

Various other camera systems of diffusion transfer photography have been proposed.

DIFFUSION TRANSFER PROCESSING MACHINE. The negative and positive papers pass through the developer (activator solution) and are pressed into contact on passing between the rollers. A, roller. N, exposed negative paper. P, non-sensitized positive paper.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

DOUBLE SIDED COPIES. 1. A negative paper N_1 is exposed by reflex printing to one side of the original O. 2. A second negative paper N_2 is exposed to the other side of the original. 3. The two negative papers are passed through the processing machine together with a double positive paper DP, carrying a positive layer on both sides. 4. The result is a double sided positive copy.

These include materials where the negative paper is spooled up on normal roll film spool and loaded into an ordinary roll film camera. When the whole negative strip is exposed, it is fed through an alkaline activating bath in contact with a non-sensitized positive strip. The resulting prints, after peeling off the negative, can then be cut up and handled like ordinary contact prints. The negative, if made on film, can be recovered for further use (enlarging, etc.) by a fixing treatment. This system is more versatile in that it is adaptable to conventional cameras and does not need a special camera design to allow for the processing; on the other hand the pictures are not available immediately.

Colour diffusion transfer. The Polacolor process, while producing positive colour prints by a kind of diffusion transfer, differs chemically from the black-and-white silver processes described so far.

The negative material here consists of three differentially sensitized layers (green-, red- and blue-sensitive), three layers containing special dye complexes and two spacing layers. Immediately below the top (blue-sensitive) emulsion layer is a layer containing yellow dye molecules linked to developer molecules. The green-sensitive layer has associated with it a magenta dye-developer layer, and the red-sensitive layer a cyan dye-developer layer.

The three sensitive layers analyse the subject colours in the usual manner of subtractive colour materials. During processing—initiated by spreading an activating jelly between the negative film and a positive paper—the dye developer molecules begin to diffuse into the neighbouring sensitized layers, and there develop the negative images. During development the dye molecule is fixed in the negative layer wherever a negative image is developed.

The unused dye developer molecules diffuse into the receiving layer of the positive material, forming a positive colour image there. The positive material also contains a layer of acid molecules which towards the end of processing neutralize the alkaline activator. When processing is complete, the positive print is peeled off the negative, and now carries a colour image consisting only of the dyes. The process depends greatly on the controlled diffusion of the dye developer molecules, achieved by the spacing layers and by careful balancing of the exposure and development times.

The process is also adaptable in principle to producing colour transparencies (by using a positive material coated on film base); the colour negative is not however recoverable.

DIMENSIONAL STABILITY. Ability of a material to resist changes in size caused by changes in temperature and humidity, processing and ageing. It is normally expressed as a percentage change in the length or width of a material. The term dimensional stability is generally used in relation to emulsions coated on film base, as glass plates can for most practical purposes be regarded as being completely stable. Such very small changes as occur with these are mainly due to creep of the emulsion or substratum across the glass surface during processing rather than expansion or contraction of the glass itself.

With certain exceptions, photographic papers are subject to such large variations in size, as well as distortion, that they are not used where dimensional stability is important and, therefore, most photographic manufacturers do not publish figures for them. Some manufacturers supply special papers with waterproof base, or a laminated paper which has a thin metal foil sandwiched between two layers of paper. The latter type of paper has a high degree of stability.

Film has several advantages over glass; it is less liable to damage, easier to store and transport, and—in the graphic arts—permits the use of contact screens for halftone work. In addition, film is easier to handle, for example

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

when making a composite negative or positive by patching up separate films or when making overlays. For these reasons, recent years have seen the introduction of more stable film bases. Although none of these is as stable as glass they are a considerable improvement over the commonly-used cellulose acetate. Any material, however, which is flexible is also capable of being stretched or compressed.

The factors affecting the dimensional stability of a photographic base are:—

(a) Its coefficient of thermal expansion, i.e., its ability to withstand changes in temperature.

(b) The degree to which it will absorb moisture and, therefore, its ability to withstand changes in relative humidity.

(c) Its tensile strength or ability to withstand the forces exerted by the gelatine coating which is itself subject to shrinkage and expansion.

(d) Its chemical inertness inasmuch as this affects the loss of plasticizer or other constituents during processing or ageing.

In practice, the dimensional change of a photographic material is the result of the sum of the temperature and humidity changes and the processing conditions. Changes in temperature invariably occur at a constant dew point and are therefore accompanied by changes in relative humidity. The changes may be additive or, more likely, may tend partially to cancel one another.

Changes in size due to ageing or processing are usually permanent, whereas changes due to moderate variations of relative humidity or temperature are reversible, i.e. if the original conditions are reproduced the base will return to its original dimensions.

TEMPERATURE AND HUMIDITY CHANGES OF EMULSION SUPPORTS. Top: *Average per cent change (relative) in size per degree C at constant relative humidity.* Bottom: *Average percentage change in size with changes in relative humidity for values between 20 per cent and 100 per cent, for the same emulsion and backing coated on different bases of similar thickness.* A, *glass (not affected by humidity change).* B, *triacetate.* C, *polystyrene.* D, *polycarbonate.* E, *polyester. Polystyrene has the best resistance to humidity changes, but is less satisfactory in temperature stability. Polyester to date provides the best compromise.*

Temperature Changes. All the bases tend to expand with an increase in temperature and contract with a decrease in temperature. This change in size with temperature change is greatest for triacetate, polystyrene and polycarbonate bases, less for polyester, and least for glass. It is independent of the thickness of the base or the thickness of the emulsion or backing, within the normal limits of thickness as used in the photographic industry.

Humidity Changes. All photographic films tend to become larger as the relative humidity (R.H.) increases and to become smaller as the R.H. decreases.

Triacetate and polycarbonate bases have a higher water absorption and lower tensile strength than polyester or polystyrene. They are, therefore, more subject to changes in R.H. not only in the uncoated state but also to a greater degree when coated. Owing to their lower tensile strength they are less able to withstand the stresses exerted by the gelatin, when this expands with the absorption of water and contracts with the loss of water.

Both the thickness of the gelatin coating and the thickness of the base have an effect upon the dimensional stability. The thicker the gelatin coating the greater will be the force that it exerts upon the base. This is why continuous tone films which have a higher coating weight than high contrast films are coated on thicker bases, such as ·007 in. polyester or ·01 in. polystyrene.

Processing. Changes in size of a film due to processing are permanent and irreversible. Certain bases which are not so inert, such as triacetate, suffer a loss of plasticizer and solvent during processing and this results in a permanent size change. Even the inert film bases such as polyester which contains no plasticizer or solvent, however, show a permanent though smaller change due to the gelatin coatings. Processing can be regarded as an extreme change in R.H. which causes a permanent change in the gelatin coating, even when coated on glass. This change is usually a shrinkage which occurs with drying, but in the case of inert bases such as polyester is dependent upon the relative humidity to which the film was conditioned before processing. With a low R.H. before processing, and reconditioning the film to the same R.H. after processing, there will be an increase in size. A high R.H. equilibrium before and after processing will result in a shrinkage which is greater with increasing silver/gelatin ratio and with increasing area of developed silver. Thickness of gelatine coating and thickness of base also have to be taken into account.

Ageing. All films show a decrease in size with ageing. This change is caused by the shrinkage

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

of the gelatin, gradually causing a plastic flow of the film base. In addition, bases such as acetate show a change due to loss of residual solvent.

Storage conditions play a large part in the degree and rate of change. High temperature will increase the plastic flow of the base. Low humidity storage tends to increase the compressive force exerted by the gelatin and, therefore, increases the shrinkage.

Certain conditions can be chosen which will minimize the change in size of a photographic image, or will help to keep the amount of change constant so that it can be allowed for.

Ideally the complete area in which films are to be handled should be air-conditioned. Temperatures from 14° C–20° C and R.H. from 50–60 per cent are about the optimum conditions.

Films should be conditioned to the temperature and R.H. of the working area by keeping in unsealed packages for at least 24 hours before use.

Excessive temperatures should be avoided during exposing as this can cause a permanent change in film size.

During processing the temperature and time in each bath, particularly during washing, should be controlled within reasonable limits.

The rate of drying can cause large variations in the change of size. On certain bases the processing shrinkage already referred to can become an expansion if the films are dried very quickly. Conditions of drying should, therefore, be standardized as far as possible.

Actual figures for the dimensional stability of the various bases available vary from one manufacturer to another. D.A.H.

DIMETHYL GLYOXIME. Used in nickel toners, as it forms a red compound with nickel.

Formula and molecular weight: $(CH_3)_2(CNOH)_2$; 116.

Characteristics: White powder.

Solubility: Insoluble in water, fairly soluble in alcohol.

DIMETHYL-PARA-PHENYLENEDIAMINE HYDROCHLORIDE. Para-(dimethylamino) aniline hydrochloride. Developing agent for direct colour development with colour couplers.

Formula and molecular weight: $(CH_3)_2NC_6H_4NH_2HCl$; 172·7.

Characteristics: White powder. Similar to diethyl-para-phenylenediamine hydrochloride.

Solubility: Fairly soluble in water.

DIMMER. Electrical control which makes it possible to adjust the light given by a lamp or bank of lamps to any value up to and including the full normal brightness.

Dimmers usually consist of a number of open spirals of resistance wire connected in series with the light. The spirals are arranged so that movement of a control knob or arm short-circuits or disconnects them progressively until, in the extreme position, no effective dimming resistance is left in circuit and the full power of the supply is applied to the lamp. Alternatively, the circuit may start with a high resistance in series with it and movement of the control may add spirals in parallel, allowing more and more current to pass up to the maximum value.

DIMMERS. Top: *Sliding resistor for adjusting the current taken up by the lamp, thus controlling its brightness.* Bottom: *Fixed dimming resistor with short-circuiting switch.*

Series-parallel Dimming. When the illumination is provided by more than one lamp of the same kind, a 2-pole double throw switch may be used to give one stage of dimming by connecting the lamps in either series or parallel. In the parallel position the lamps give their full brilliance; in the series position the voltage applied to each lamp is halved and the light is reduced to less than one-quarter.

The series-parallel arrangement is useful for increasing the working life of Photoflood lamps. Two lamps connected in series give enough light for focusing and arranging the subject and the switch has only to be thrown into the parallel position to make them give their maximum brilliance. This lengthens the life of the lamp in two ways; the full brilliance is used only for the brief taking interval, and not for the lengthy business of arranging the subject, and the filament lasts longer because its

SERIES-PARALLEL SWITCH. With two switches wired up as shown and both open, the lamps are dimmed. They come to full brilliance on closing the switches (usually connected by a bar).

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

temperature is increased in two easy stages instead of being switched to its full value.

Chokes. Lamps operating on alternating current may be dimmed by a variable choke of the type used for ballasting carbon arcs. Lamps on direct current circuits can only be dimmed by a variable resistance dimmer and not by a choke or tapped transformer.

Dimmers are not normally used in subject lighting circuits because they would make it impossible either to predict or repeat the correct exposure. They also alter the colour temperature of the light. Their principal use is in projectors, for adjusting the screen brilliance, and in cinemas, for raising and lowering the house lights.

D.I.N. SPEED. System of stating emulsion speeds, as laid down by the Deutsche Industrie Norm (German standards organization).

See also: *Speed of sensitized materials.*

DIOPTER. Unit expressing the power of a lens, mainly used by opticians. It is the reciprocal of the focal length in metres. When the power of a lens is stated in diopters (= d), its focal length is given by 100/d in centimetres, e.g., a lens with a power of 17 diopters has a focal length of 100/17 = 5·88 c.m. The power of supplementary close-up lenses used in photography is generally expressed in diopters.

See also: *Supplementary lens; Weights and measures.*

DIRECT CURRENT (D.C.). Term for electric current produced by a steady potential, e.g., generated by a dynamo or simple cell.

DIRECT VISION FINDER. Any form of viewfinder through which the subject is looked at directly, as with a telescope, instead of by reflection from a mirror.

DISCHARGE LAMP. Light source in which an electric current passes through a gas enclosed in a glass or quartz envelope.

The colour of the light is governed by the composition of the gas, and not by its temperature as it is in a filament or carbon arc lamp.

Mercury Vapour Lamp. Mercury vapour is the commonest source of discharge lighting. The simplest lamp of this type—the Cooper-Hewitt—consists of an evacuated glass tube fitted with a graphite electrode at each end and containing a small amount of mercury. By tilting the tube, mercury is made to bridge the electrodes, and start an arc. The heat of the arc turns some of the mercury into a vapour which glows with an intense light, rich in ultra-violet, violet and yellow-green rays, but containing practically no red.

The operating voltage depends on the length of the tube, and is usually below 100 volts, and a choke or resistance is necessary,

DISCHARGE LAMPS. Top: *250–400 watt high-pressure mercury vapour lamp. The discharge takes place inside a pressure tube sealed into the outer bulb.* Upper centre: *80–125 watt high-pressure mercury vapour lamp.* Bottom: *Two forms of compact source lamps for projectors and studio use.*

as for most arc lamps. By connecting two lamps in series, less "ballast" is needed and the efficiency of the system is greatly improved.

Low-pressure mercury vapour lamps are made to work off both D.C. and A.C. supplies. The visual efficiency is less than 20 lumens per watt, but the light is highly actinic. This type is used extensively in process work and plan copying.

Improved Types. If the pressure of the gas is increased, its resistance also increases. This means that the tube can be made shorter and still give the same—or more—light for the same electrical consumption. Lamps based on this principle have a short quartz tube an inch or more in length according to the power. The tube works at a pressure of 1 atmosphere and is surrounded by a partly evacuated bulb to cut down heat radiation and maintain the tube at an efficient working temperature. This type of lamp is made in ratings from 80 to 400 watts and has an efficiency up to 45 lumens per watt.

A modern development of these lamps is the tungsten-ballasted mercury vapour lamp. It also contains a tungsten filament which takes the initial surge of current when switching on and therefore does not need choke gear, so that the lamps can be plugged directly into the supply line. Another advantage of this type is that the tungsten filament, which fades down to a bright

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

red colour as the mercury tube brightens, adds a useful amount of red to the light which is normally deficient at that end of the spectrum.

Lamps working at still higher pressures—up to 100 atmospheres—are nowadays widely used in photography. In the lower ratings—up to 1,000 watts—they are used for portraiture and spot lighting. More powerful lamps consuming several kilowatts are used in film studios. The operating voltage of such lamps may exceed 1,000, and the efficiency may be as high as 70 lumens per watt. As the concentrated discharge develops an appreciable amount of heat, which would even melt the quartz used, some form of water-cooling is necessary with the more powerful units.

A special type of high-pressure mercury vapour lamp known as the compact source lamp has been produced for projection in ratings from 2½ to 10 kilowatts at normal supply voltages.

These lamps consist of two electrodes, and sometimes a heated coil for striking, enclosed in a quartz bulb and surrounded by an evacuated bulb to maintain the discharge temperature. High working pressures are used, but normal voltages are sufficient since the impedance of the discharge is comparatively low.

Spectral Composition. The light of the mercury vapour lamp has no continuous spectral composition but consists instead of isolated spectral lines. In the case of the Cooper-Hewitt lamps the visible output consists almost entirely of two lines in the violet, one in the yellow-green, and one in the yellow region of the spectrum. This results in very distorted colour reproduction when the lamp is used for general photography such as portrait work; skin defects are emphasized (being red in colour, any light source deficient in red will accentuate them).

DISCHARGE LAMP SPECTRUM. A gas discharge lamp emits light of specific wavelengths only, and not a normal continuous spectrum. Top: Sodium lamp with single yellow waveband. Bottom: High-pressure mercury vapour lamp with pronounced individual lines but also a continuous background spectrum.

With high-pressure lamps the colour of the light is improved, since a low-intensity continuous background spectrum appears, including orange and red rays.

A further improvement in the mercury vapour lamp is produced by including some zinc or cadmium vapour in the tube. This increases the proportion of red rays and makes the light suitable for normal black-and-white, or even colour, filming.

Fluorescent lamps (below) are another type where the spectral composition has been balanced more evenly by additions to the interior of the lamp.

Sodium Vapour. Sodium vapour gives a light of similar electrical characteristics to mercury, but the colour produced is the familiar yellow of many of our road lighting systems. This lamp is suitable for photography with yellow-sensitive materials; the light is however monochromatic and contains only yellow. Hence all objects not reflecting yellow will appear black. The visual efficiency of a sodium lamp may be as high as 70 lumens per watt.

Xenon and Other Gases. Xenon high-pressure discharge lamps are fairly widely used for film and television studio illumination and also are gradually replacing arc lamps in motion picture projectors. Most electronic flash tubes are also in effect Xenon discharge lamps.

Like the high-pressure mercury lamp, the Xenon arc needs water cooling in the larger units.

They are used as illuminators in process camera work, for high-power lighting in high speed cinematography, etc. Small Xenon lamps have also appeared in narrow gauge cine projectors for home use.

Xenon lamps for projection purposes are usually compact source types; those for studio and graphic arts use may be strip sources in lengths up to 2 feet or more.

Xenon lamps also lend themselves to pulsed operation. In one unit for high-speed cinematography the lamp can operate for 2 seconds at a power of up to 7½ kW. Another pulsing Xenon lamp for motion picture projectors gives light pulses at a rate of 72 per second, in synchronism with the intermittent film transport, so that the projector needs no rotating shutter.

The visual efficiency of the Xenon arc is over 70 lumens per watt and the colour quality of the light is sufficiently similar to daylight to permit its use as an exposing light for photography with daylight type colour film.

Argon and Krypton have also been used

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

XENON LAMP SPECTRUM. While the xenon lamp emits its radiation in discrete bands (the peaks in the curve) it also yields a somewhat lower level of radiation throughout the spectrum and is therefore suitable even for colour photography.

either on their own or in combination with Xenon in high pressure discharge lamps.

Fluorescent Lamps. A large proportion of the radiations emitted by a mercury vapour lamp lies in the invisible, ultra-violet region—i.e., between 3,650 and 3,663 A. These radiations are useless for ordinary room lighting but they cause certain substances to fluoresce visibly. By coating the glass envelope with such substances the lamp is turned into a useful and highly efficient light source. This is the principle of the familiar tubular fluorescent lamp widely used for lighting public buildings and occasionally for domestic interiors.

As the frequency of the supply causes the light to fluctuate, certain precautions are necessary when making short instantaneous exposures by this form of illumination.

Fluorescent lamps, like other discharge lamps, must be connected to the supply through special control gear. F.P.

DISCOVERY OF PHOTOGRAPHY

Technical histories are histories of inventions—overflowing with argument about dates, names and precedence. These arguments are set off by historians who stress the importance of their own discoveries and are kept going by competing national vanities. But behind the smoke-screen of controversy there is a pattern of continuity, logic and progress. People, places and products matter less than we may think. In technological progress a man and his ideas are never quite alone. As many inventions are mutations of available knowledge, more than one person may hit on the same idea at the same time. The invention that matters most need be neither the first nor the best; it is the one that arrives at the right moment, strikes fertile conditions and leads to practical success.

The idea of photography is a synthesis of two lines of experience—both old. One is, that certain substances are sensitive to light; the other is, that light entering a dark room or box through a small hole will draw an inverted image of what is outside opposite to the hole. The chemical and optical lines of progress converge and where they intersect—photography is discovered.

LIGHT SENSITIVITY

It was noted thousands of years ago that foliage turned green in light and that light would produce purple dyes from the slime of some Mediterranean snails. It was common knowledge that certain colours were bleached by the sun. The respective functions of light, heat and air may not have been very clear to the ancients, and medieval alchemists added to the confusion by looking for mysterious chemical powers emanating from the heavenly bodies.

Early Experiments. Then in the seventeenth century the quest for exact knowledge based on experiments gradually made itself felt. In 1663 Robert Boyle, one of the founders of the Royal Society, described many chemical reactions and the resulting changes of colour. He mentioned that silver chloride turned dark under exposure; only he thought that this was caused by "air". In 1725 Johann Heinrich Schulze, a professor at the Universities of Altdorf and Halle, was looking for phenomena of phosphorescence and in doing so accidentally exposed to light a suspension of chalk in silver nitrate; he recognized, tested and correctly explained the darkening action so caused. In 1737 Jean Hellot, member of the Académie des Sciences de Paris, described invisible inks containing silver nitrate and gold chloride, which became legible when exposed to "air". In 1757, Giovanni Battista Beccaria, Professor of Physics at Turin, discovered the sensitivity of silver chloride and demonstrated that it was not air but light that turned his specimen blue-violet. It is unlikely that these scientists knew much of each other's work.

But by the second half of that fabulous eighteenth century its virile intellectual forces were beginning to draw together. Individual discoveries were followed by clear recognition of principles, planned research by broad literary surveys. In 1772, Joseph Priestley, fellow of the Royal Society, published his *History and Present State of Discoveries Relating to Vision, Light and Colour*, the first comprehensive description of the chemical action of light. In 1777, Carl Wilhelm Scheele, the Swedish chemist, published his dissertation *Aeris atque Ignis Examen Chemicum*, introducing the prismatic solar spectrum for the investigation of light sensitivity and ammonia as an agent for separating blackened from unchanged silver chloride.

CC-0. Asamnigam Digital Preservation Foundation, Chandigarh

In 1782, Jean Senebier, librarian of the city of Geneva, published his extensive experiments in colour sensitivity.

Thomas Wedgwood. The enthusiasm for experimenting and the number of experimenters grew rapidly. Among them was Thomas Wedgwood, fourth son of Josiah Wedgwood, the famous potter. In 1802 his friend Humphry Davy, later president of the Royal Society, published a report about Wedgwood's method of copying glass paintings or drawings on paper or leather which were treated by silver nitrate or silver chloride. He also described how silhouettes were made by the same method. (Jacques Alexandre César Charles, the versatile French Academician and popular lecturer, was said to have produced similar profiles by light before Wedgwood had done so, but there is no evidence that would confirm this belief.) Wedgwood had to keep his images drawn by light in darkness and could show them only by candle light; he found no way of making his work permanent—although Scheele's experience with ammonia should have been known among his friends. He was also unsuccessful in his attempts to make similar pictures in the camera obscura. There is an air of casualness about Wedgwood's efforts and Davy's summary of them. Wedgwood died three years after it was published, 34 years old. He touched the threshold beyond which photochemical experiments were made to serve graphic ends.

THE CAMERA IMAGE

Knowledge of the camera or, at least, of its principle has been ascribed to Mo Tzu in China of twenty-five centuries ago the Greek philosopher Aristotle (384–322 B.C.), the learned Arab Ibn al Haitam (965–1038), the English friar Roger Bacon (1214–94), the Hebrew scholar Levi ben Gershon (1288–1344) and others. But some of these assumptions are based on imaginative readings of barely more than sketchy remarks.

The Camera Obscura. That giant of the Renaissance Leonardo da Vinci (1452–1519), described the working of the camera obscura quite fully; only his account—confined to his manuscripts in mirror writing—did not become public property for centuries. An illustration of the camera obscura was actually published in 1545 yet the invention of the pinhole camera is still mostly linked with the name of Giovanni Baptista della Porta of Naples who gave a very clear description of it in his *Magia Naturalis sive de Miraculis Rerum Naturalium*, the first edition of which appeared in 1558.

In 1568, the Venetian nobleman Daniel Barbaro suggested the addition of a biconvex lens to the camera and of a diaphragm to improve the definition. Twenty years later, in a new edition of his work, Porta also mentioned the use of a lens as well as of a mirror to right the reversed image. In Porta's time a whole room was used as a camera obscura.

The seventeenth century, recognizing their usefulness to artists in drawing exact perspectives, brought portable cameras. The astronomer Johannes Kepler used one for topographical sketches in 1620, the Jesuit Athanasius Kircher illustrated a large portable model in 1646, the Praemonstratensian Johann Zahn described several small box reflex cameras in 1685.

Improvements. But it is the eighteenth century that made the camera obscura really popular; the improvements were both mechanical and optical. The shape was changed, among others, into that of tables, a sedan chair or a small tent that fastened to a drawing desk with the viewing piece turned into a reflecting periscope. Some cameras were equipped with a concave drawing board to compensate for marginal failings of the lens. Eventually, in 1812, William Hyde Wollaston replaced the old biconvex lens by a meniscus with a stop giving uniform distribution of reasonable sharpness over the whole field.

Now the image was coming out bright and sharp enough to evoke a desire in the draughtsman to catch this picture by means quicker than his hand. It certainly suggested this possibility to Fox Talbot in 1833 when he tried to sketch landscapes with the aid of a camera lucida on Lake Como (". . . the idea occurred to me . . . how charming it would be if it were possible to cause these natural images to imprint themselves durably, and remain fixed upon the paper!").

Retaining the Image. The vision of a mirrored view caught for good is probably as old as human imagination.

The Roman poet Publius Papinius Statius (40–96 A.D.) has it in some verses of *Silvae*.

In *Gyphantie*, a piece of science fiction from 1760, Charles-François Tiphaigne de la Roche romances about a subtle sticky substance which, coated on a piece of canvas, has only to be held before any object to depict it instantaneously.

Yet his were fancy dreams of magic at a time when down-to-earth practitioners of magic did not get beyond using silver solutions to make writing appear from nowhere or to turn a white man into a negro. Magicians' handbooks of the late eighteenth century have plenty of good advice to give on such subjects as well as entertaining uses of the camera obscura. However, when Talbot, returning from Italy, concentrated on the problem of marrying chemistry to the camera others were way ahead of him.

NIÉPCE

Joseph-Nicéphore Niépce of Chalon-sur-Saône, born 1765 into the well-to-do Burgundy bourgoisie, retired as a subaltern from a short army service and devoted himself to technical

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

inventions. In 1813 he turned to lithography, which had recently been imported into France. Niépce could not draw and looked for ways of copying designs on to the lithographic stone. Thus in 1816 he became interested in the problem of producing images in a camera by light on sensitive materials.

Heliography. He made several cameras; one of them was the size of a jewel box. The dimensions of his cameras were determined by the focal length of the lenses he found. He fitted these in metal tubes and also used bellows. He improved definition by a stop and turned that into the iris diaphragm. He tried stone, glass, metals and paper for materials and sensitized these with a variety of substances following up references in the expanding literature of chemistry.

Niépce's progress was slow and groping; he worked for twenty years with admirable persistence yet apparently was handicapped by provincial isolation. His experiments were dominated and probably misdirected by the combined idea of a camera-made image that would also serve as a printing plate. Niépce called his process Heliography and applied that name both to images produced in the camera and to designs traced in contact from art work.

Limitations. His first camera images, in 1816, were weak negatives on paper treated with silver chloride and poorly fixed in nitric acid. He was aware of the problem of having to reverse the tones and preferred searching for alternative substances that would give him direct positives. After 1822, he settled down to an asphalt varnish on metal and glass and used a mixture of oils as a solvent for fixing the image. Niépce's varnish was not suited to recording tone values in camera views and, as sometimes a whole day was required for exposing these, the sun moving around the horizon also interfered with whatever modelling the material would yield. Niépce succeeded in taking a view in the camera in 1826, but his best heliographs were line subjects, engraved plates or prints made from engraved plates.

Thus Niépce invented a form of photography but he left it in a technical *cul-de-sac* waiting for Daguerre to find a way out.

DAGUERRE

Louis Jacques Mandé Daguerre, born 1787, was a gifted scenic painter and ingenious showman. His Diorama, opened in 1822, was acclaimed as one of the great attractions of Paris; it combined panoramic views with changing light effects and foreground props that blended into a colourful and realistic spectacle.

Daguerre, being interested in the interplay of light and perspective, made use of the camera obscura for sketching. He is supposed to have stimulated its improvement by the opticians, Vincent and Charles Chevalier, who equipped it with a double lens which they developed from Wollaston's meniscus. Daguerre discussed with the Chevaliers his ideas of catching the images in the camera obscura and even claimed to have succeeded in doing so.

Partnership with Niépce. In January 1826, on hearing about similar experiments by Niépce, the Chevaliers passed on his address to Daguerre. Daguerre wrote to Niépce with little loss of time; Niépce replied evasively. Twelve months later, in January 1827, Daguerre wrote again and Niépce now made careful inquiries about his correspondent. In August 1827, on his way through Paris, Niépce visited Daguerre and left impressed. He was now well over sixty, a tired provincial, financially much embarrassed, and in January 1828 he returned from London with a refusal of the Royal Society to take note of his invention as he was not ready to tell how he arrived at it. Daguerre was twenty-two years his junior, a very live Parisian, well off and successful in his undertakings.

By the end of 1829 the two arrived at a formal contract to run for ten years, agreeing to pool their secrets, mutually to improve upon their results, to publish their invention at the proper time under the joint names of Niépce and Daguerre and equally to share in the profits. To execute the agreement Daguerre came to Chalon and Niépce demonstrated his process. He also handed over a memorandum of detailed instructions how to use it. Daguerre does not seem to have disclosed anything; it is doubtful whether he had much to disclose at this stage.

The partners never saw each other again. Niépce died in 1833.

When Niépce and Daguerre signed their agreement in 1829 each seems to have expected too much from the other.

Niépce, who had been inclined to blame his optical equipment for slow progress, readily believed Daguerre's over-statements about his improvements to the camera obscura. Daguerre, whose chemical experience was sketchy, must have overrated the flexibility of Niépce's knowledge.

In any case when, in 1831, Daguerre repeatedly wrote to Niépce pressing for experiments with silver iodide, Niépce proved to be unreceptive. He thought he knew the substance from earlier trials, he was worried about getting negative images and he saw no way of fixing them. Eventually Daguerre must have realized that he was on his own and shut himself up in his laboratory.

Daguerre's Progress. Nobody was permitted to watch Daguerre's work and nobody really knows what he did except that for a few years he worked feverishly. His progress is related in a number of episodes which are colourful and plausible enough to have originated from a man with an obvious flair for effects.

One story tells how, in 1823, Daguerre noticed on a freshly painted scene the image of a tree which had been projected through a

small hole in the window shutter; it was still there next day. This prompted him to try to retain images in a camera and during these trials he recalled that he had mixed iodine with the colours when painting that scene . . .

The second story tells about Mrs. Daguerre's visit, in 1827, to the celebrated organic chemist Jean Baptiste André Dumas to whom she complained that her husband was neglecting his business for the sake of dubious experiments. Dumas looked up Daguerre, but instead of discouraging him gave useful advice and promised expert help . . .

The third story is supposed to have happened in 1831; it relates to a silver spoon which, lying by chance on an iodized plate, left its perfect image on it . . .

The fourth story brings us up to 1835 when, having locked in a cupboard an insufficiently exposed iodized silver plate that had not shown traces of an image, on opening the cupboard Daguerre was surprised to see a fully developed image on it. The developing agent, found by eliminating one chemical after another that had been locked in with the plate, proved to be mercury . . .

The Process. Some of the materials used by Daguerre were used by Niépce before him; yet Daguerre's process was different. He employed silvered copper plates coated with vapours of iodine. He exposed the plate in the camera for fifteen to thirty minutes, producing an invisible or scarcely visible image. This latent image was developed by placing the plate over a vessel of heated mercury. Fine particles of the mercury clinging to the exposed regions of the silver iodide then formed a visible positive image. Finally Daguerre washed the plate in a hot solution of cooking salt, removing the unnecessary iodide and thus making the image permanent. The *Journal des Artistes* of 27th September 1835, claimed that he produced permanent images at that date, but in fact he found a way of fixing them only two years later.

It was also in 1835 that in view of his own progress Daguerre invited the son of his former partner, Jacques Marie Joseph Isidore Niépce, to accept a modified agreement changing the joint name from Niépce-Daguerre to Daguerre-Niépce. In 1837, demonstrating his latest results, he made the younger Niépce agree to drop his father's name altogether; the financial arrangements were to remain unaffected. In 1838 Daguerre's efforts to find money for a public company failed and so he turned to the influential scientist and politician Dominique François Arago for assistance in selling the invention to the French State. Rumours were helpfully afoot that "England offered to buy the secret of the process for 200,000 francs".

Official Recognition. On 7th January 1839 Arago reported to the Académie des Sciences about Daguerre's achievement. On the preceding evening the *Gazette de France* duly scooped the news. On 8th March the Diorama was destroyed by fire; Daguerre seemed ruined. On 15th June the Minister of the Interior, Tannegui Duchatel, presented to the Chamber of Deputies a bill granting Daguerre for life an annual pension of 6,000 francs and Niépce junior 4,000 francs. The bill was adopted by the Chamber on 3rd July based on the impressive exposition by Arago; the Peers adopted it on 30th July after a report by Joseph Louis Gay-Lussac, the great physicist.

On 19th August 1839 Arago, in a brilliant speech before the members of the Académie des Sciences and the Académie des Beaux Arts, described the technique in detail, sketched its history, forecast its future in the service of civilization and offered its free use to everybody. ("France has adopted this discovery and from the first has shown her pride in being able generously to donate it to the whole world".) Alas, on 14th August, Daguerre had secured a patent in England.

The building was overflowing with the cream of French intellectual life, outside Paris was buzzing with excitement and by then the whole world was listening. Ambassadors of the King of France presented daguerreotypes to courts abroad. Daguerre in return received decorations and presents from foreign sovereigns. Photography was officially born, ushered in by a beautiful gesture and in a setting of perfect stage management.

Dissent. There were dissenting voices long before the celebration. Francis Bauer, Fellow of the Royal Society, wrote a letter on 27th February 1839 to the Editor of the *Literary Gazette* of London to express the view that Daguerre's invention was the same as that of Nicéphore Niépce of whose work Bauer had proofs from 1827. Talbot wrote on 29th January to Arago and made a formal claim of priority to fixing images in the camera obscura. Hippolyte Bayard, a clerk in the Ministry of Finance, brought his own positive paper images to Arago three months before Daguerre's process was officially disclosed in August.

Daguerre's was really the wrong invention, yet launched so intelligently and with such force that other ideas could barely keep afloat in its wake. At a time when factories and railways were preparing great social changes which would soon produce mass demands for new arts, the daguerreotype presented an exquisite small silver image that was as unique and almost as laborious to duplicate as an artist's miniature painting. Niépce had been instinctively groping for the desirable solution when he tried to link his camera with lithography; but he became bogged down in the mutual incompatibility of the two techniques.

It was left to Talbot, a distinctly feudal figure, to grasp the essentials of such a democratic art and thus open the epoch of negative-positive photography—the functional method for producing with ease any number of prints from the original made in the camera.

TALBOT

William Henry Fox Talbot, born 1800, was the only son of William Davenport Talbot of Lacock Abbey in Wiltshire and Lady Elizabeth Fox Strangeways, eldest daughter of the second Earl of Ilchester. The Talbots had resided at the thirteenth century Abbey since the days of Henry VIII. Fox Talbot was educated at Harrow and Trinity College, Cambridge. He had a keen, exacting and versatile mind and developed interest in botany, mathematics, chemistry, physics, astronomy and archaeology. He wrote some tales in prose and verse which he hoped would be set to music and later learned works on classical research, on the book of Genesis and on English etymology. He had a wide knowledge of languages and travelled a great deal. For a couple of years he sat in Parliament and he was a Fellow of the Royal Society. Talbot's photographic activities cover merely a phase of his life and even whilst that phase lasted they were only a facet of it.

Photogenic Drawings. On some of his frequent and extensive Continental tours in the eighteen-twenties he had again and again attempted to make use of the camera obscura for sketching. Late in 1833 he became impatient about his own lack of success with the camera lucida (Wollaston's prismatic device for joint viewing and drawing the scene) and on his return to England in early 1834 he settled down to tackle the problem of capturing camera images by chemistry. Of Wedgwood's experiments he learned only later. It was suggested that he may have heard of Niépce's work as well. In any case by then the basic idea which Talbot pursued was to such an extent "in the air" that he could have hardly imagined it to be wholly original.

He started, though, from scratch. First he treated paper with silver chloride and on this sensitive material he stencilled in contact by light negative patterns of botanical specimens, lace and similar objects. He neutralized sufficiently the unexposed parts by washing the paper with a strong solution of common salt or potassium chloride to retain an image for some time. By 1835 he was able to produce tiny negatives by exposing them for half an hour in small locally-made cameras, which his wife referred to as "mousetraps".

When the news came from Paris in January 1839 about Daguerre's invention Talbot hastened to draw attention to samples of his "photogenic drawings" which happened to be in London; they were shown by Michael Faraday to the Members of the Royal Institution on 25th January. Talbot showed them to the Royal Society on 31st January and published his methods on 21st February under the title *Some Account of the Art of Photogenic Drawings; or, the Process by which Natural Objects may be made to Delineate themselves without the Aid of the Artist's Pencil.*

Talbot's friend, the astronomer Sir John Herschel, became particularly interested. In a letter to Talbot, dated 28th February, he made use of the word "photography". This word also appears on 25th February in the *Vossische Zeitung* of Berlin in a notice by the astronomer Johann von Maedler; Herschel and Maedler knew each other. The same word as a verb and its adjective "photographic" does crop up even earlier in Herschel's private writings. Herschel also coined the terms "negative" and "positive". More importantly it was Herschel who suggested sodium thiosulphate (hypo), the properties of which he discovered back in 1819 and which was to become the classic fixing agent.

With Herschel's consent Talbot wrote about this method of fixing on 15th March to the physicist Jean Baptiste Biot who published the letter in the *Comptes Rendus* of the Académie des Sciences; Daguerre made use of it.

Talbotype. At the same time Talbot sent news about having improved the sensitivity of his process by using silver bromide. In the autumn of 1840 he switched to silver iodide, also used by Daguerre, and under strikingly similar circumstances to those experienced by Daguerre he accidentally discovered that the exposure time could be greatly shortened by aiming only at a latent image and developing it after exposure. Talbot confined this technique to making negatives and continued to use silver chloride paper for printing out positives. He named his developer gallo-nitrate of silver and his new process Calotype, later Talbotype.

From 1841 onwards he protected his processes with a number of patents and demanded royalties for their use.

In 1844 he published *The Pencil of Nature*, which relates the story of his work, illustrating it impressively with a number of his own Calotypes: it is as telling a monument as any inventor could erect to himself.

Restrictions. Talbot's was the right invention—but not very happily put over. He claimed to have spent £7,000 on photography (about £28,000 in present value) and naturally hoped that his invention would make a fortune. Whilst all his scientific activities reveal him as an amateur in the best sense of that word, he rigidly watched over his photographic patents, claiming and patenting also improvements and discoveries made by others, and considering himself entitled to do so as the inventor of the calotype.

His real motives were probably less one-sided than the comments either of his admirers or of his critics. Pre-occupation with figures since early childhood and carefully balanced accounts of his personal expenditure suggest that he liked to know where he stood and was not indifferent towards money.

Talbot was bound to be indignant about Daguerre's cutting across his path, his lack of fairness in securing the protection of a British patent for the supposedly "free" French

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

invention and, last but not least, about the greater commercial success of the competing French process.

Being concerned with respectability and appearances Talbot opened a photographic printing establishment for the making and sale of calotypes, and a commercial portrait studio —under the name of employees. Even when put under some pressure from the Presidents of the Royal Academy and the Royal Society who appealed to him to loosen his grip that threatened to handicap British progress, in a letter to *The Times* dated 30th July 1852 Talbot, whilst somewhat belatedly freeing his method of photography for scientists, artists and amateurs, still continued to insist on licensing portraiture for profit by the collodion process—the only worthwhile commercial application of camera work in those days. The relations between Talbot and some contemporary photographers were, in fact, such that when in 1853 plans were laid for the first Photographic Society in England, Talbot could not be persuaded to become its president.

Eventually, 1854, Talbot abandoned his patents once he lost his action against Silvester Laroche, a professional who practised the new collodion process. In the course of that case it must have been particularly disconcerting for Talbot to have to face the evidence of the Reverend Joseph Bancroft Reade, who proved that he had used a substance similar to Talbot's "gallo-nitrate of silver" before Talbot had it patented—allegedly knowing that the idea was not quite his own. (Reade used tannin as an accelerating influence in the blackening process before and during exposure whilst Talbot more decisively employed it for developing the latent image.)

BAYARD AND OTHERS

Another very disappointed man was Hippolyte Bayard of Paris. In 1840 he took a picture of himself in the nude captioning it thus "This corpse is M. Bayard . . . The Academy, the King and all who have seen his work admired it just as you do now. This brought him honour but not a penny. The Government who have done too much for M. Daguerre would do nothing for M. Bayard. So the wretch has drowned himself . . ."

The Late-comer. Born 1801, young Bayard watched his father making use of the sun for bleaching patterns on to ripening fruit through stencils. The boy repeated the game on paper which he dyed with safflower. He may have embarked on more serious experiments after 1837 but it is also possible that he only talked about them. He did begin work on 20th January 1839, i.e., after Arago's preliminary report on Daguerre and before Talbot's work became public.

Bayard fed into his camera moist paper which had been treated with silver chloride, then blackened by light and finally immersed in a weak solution of potassium iodide. He obtained a positive image bleached by the camera exposure, which took approximately an hour. He originally used potassium bromide for fixing. A couple of weeks after he started his experiments Bayard could show imperfect results to César Manuète Desprets of the Institut de France. Two months from his start he was handing around good prints. He brought them to Biot on 13th May and to Arago 20th May. He publicly exhibited thirty of them on 24th June.

By then, however, Arago was too much committed to Daguerre's cause, saw only complications arising from Bayard's intervention and cautioned him to be discreet. Bayard was a civil servant and his private interests were primarily artistic; he seems to have been timid and not much of a man of business. He laboured under the disadvantage of being a Frenchman in a France that had already made up its mind to celebrate a French invention of photography *à la* Daguerre. Because of that it was even overlooked that the pictorial accomplishments of Bayard's positive paper process temporarily surpassed those of Talbot, although it neither anticipated that of the Englishman nor in any way compromised the latter's basic merit of having developed the first workable method of producing negative-positive photographs.

Other Claimants. Even within its narrow field of achievement Bayard's priority was disputed. In France, Verignon and Lassaigne claimed to have developed similar processes before him. Fyfe is reported as having described a similar method before the Society of Arts in Edinburgh 17th April 1839.

On 13th April 1839, before the Bavarian Academy of Sciences in Munich, Franz von Kobell, a professor of mineralogy, and the optician Carl August von Steinheil presented negatives on paper sensitized with silver chloride, exposed damp in a camera made of cardboard and then fixed in hypo.

There were others as well, unnoticed by historians and unimportant to history. It is as well to remember that during the previous few years there had been notices in the press about Daguerre's experiments, some of them possibly calculated indiscretions. Besides his experiments, Daguerre was busy promoting his projects. First he was angling for private finance, then he started his subscription scheme for a public company and eventually he looked for help to the State. Since 1837 he talked increasingly often and, one might guess, quite volubly to scientists, artists, businessmen and politicians. He obtained permission to make pictures of famous monuments of the French capital. He took long exposures with his heavy apparatus perched on a vehicle surrounded by curious Parisian crowds. Stories spread to England, Germany, Russia and the United States. About his

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

"LA DAGUERREOTYPOMANIE." Théodore Maurisset's cartoon published in 1839, one of many which appeared at the time on the subject, reflecting the general excitement about this revolutionary process.

secrets he kept the people guessing and no doubt many of them spent much time in doing so. It was only to be expected that some of them would guess close enough and they were also bound to try out just how good their guesses were.

THE DAGUERREOTYPE ERA

The inventor who emerged too late will always attract sympathy, whilst recognition, success and, in particular, profits often blur the view of actual achievements and distract from real merits. Daguerre's showmanship and enterprise were destined to provoke doubts and even suspicion—yet they proved to be the motive power that sped photography into the world and around the globe.

Expansion. Within a few weeks from the release of the invention in Paris, daguerrean pictures were produced in England, Germany, Austria, Switzerland, Poland, Spain and the United States. A year later the process reached Japan and China. Daguerre's own handbook of instruction went into edition after edition in France, was published during the same year in English, German, Italian, Spanish and Swedish; the next year in Hungarian and Polish.

The original instructions and Daguerre's own equipment were in wide demand. Daguerre entrusted the sale of his apparatus to Susse Frere and Alphonse Giroux et Cie (Giroux, a relation, ran a stationer's business). Daguerre's camera weighed 50 kilograms (110 lbs.) and was sold for 400 frs. (£16—or £64 at present purchasing value). But before the end of 1839 the size and weight was reduced to one-third. Daguerre's plate measured 0·164 × 0·216 m., but cameras were also made one-third, one-quarter, one-sixth and one-eighth the original plate size. Plates cost between 1 and 4 frs. according to the size, auxilliary equipment 100 frs.

The image produced in the original camera was reversed left to right. It had a cold metallic sheen which caused reflections. It abounded in fine detail but was lacking in tone contrast. In strong sunshine 15 minutes exposure was needed; in less favourable light up to 30 minutes. Portraiture was torture; the portraits looked it.

Improvements. But the diffusion of information, stimulus and research that follows in the wake of major discoveries soon produced improvements. Mutations and duplications of closely related ideas are common at such stages in the development of any invention; claims of priority correspondingly frequent and on the whole irrelevant.

The sensitivity of the plates was increased by using a second halide (bromide or iodo-chloride of silver) as an accelerator. Such combined sensitizers were initiated by John Frederick Goddard and Antoine Frances Jean Claudet of London and Franz Kratochwila of Vienna.

CC-0. Kashmir Collection of Kashmir Digital Preservation Foundation, Srinagar

In order to get stronger blacks, Baron Armand Pierre de Séguier devised better methods of polishing the metal plates; John Adams Whipple of Boston, Massachusetts, introduced machinery for the job.

Hypolite-Louis Fizeau of Paris turned the cold metallic glare of the daguerreotype into a deep purplish tone by adding gold to the fixing process; this also made the image more stable.

Johann Baptiste Isenring of St. Gallen in Switzerland found methods of retouching the eyes, gilding ornaments and colouring the face. So did others in England and France.

Prisms added to the lens reversed the image and thus normalized architectural views and other scenery (but again lengthened the exposure). Curiously enough, no great need for this reversal was felt by the sitters for portraits, who readily accepted the likeness they knew from their mirrors.

An ingenious camera with a concave mirror replacing the lens so shortened the exposure that it enabled Alexander Wolcott to open the world's first portrait studio in New York at the beginning of March 1840. One year later Richard Beard using the same camera opened the first photographic studio in Europe at the Polytechnic Institution, London, on 23rd March 1841.

The mathematician Josef Petzval of Vienna brought about a decisive turn in the fate of Daguerre's process by producing, in 1840, a new double lens with separate front and back components which, having an aperture of $f\,3{\cdot}6$, was thirty times faster than the Chevalier lenses originally used in Daguerre's cameras. These lenses, combined with the improved sensitizing methods and smaller plate sizes, reduced the time of exposure from a quarter of an hour to as little as 15 seconds. By 1841 Natterer in Vienna took military parades with an exposure of 1 second and Gaudin took Paris street scenes at one-tenth of a second—or so he said. Petzval's lenses were described abroad as "système Allemande" although neither the lens nor the designer came from Germany. The sales appeal of that phrase became so overwhelming that lens makers in other countries also engraved it on their mounts—sometimes irrespective of the performance of the product. Petzval got little financial benefit from his revolutionary design, quarrelled with those he thought deprived him of his dues and died a misanthrope. But he made portraiture a popular reality everywhere.

Portraiture. Cheap, quick and life-like portraiture was the key to the rapidly expanding boom of Daguerre's process. To have his image reproduced and perpetuated satisfied a deep urge in man. Sculptors, painters and lithographers could serve only the few who had the leisure to sit for them and the means of paying for a competent artist's skill. There were, of course, itinerant and back-street artists who would charge modest rates and produce quick results but their work was mostly crude and the likenesses but sketchy. Technical tricks and tools to speed up the process and trace more exactly true likenesses had been sought for since the Renaissance and became numerous in the eighteenth century (silhouettes since 1760, the Physionotrace since 1789). The mid-nineteenth century did not at first work up a snobbish distinction between hand-made and not quite hand-made arts and so high and low alike rushed to have the capabilities of the camera tried out on their own faces. The artists themselves saw in it merely a new tool, an easier way to do the job and earn more money.

The protests of the intellectuals came later but soon enough. The poet Charles Baudelaire was among the first to mistake popular appeal for a sign of artistic inferiority. ("The whole filthy mob rushes in like a single Narcissus to gloat over their trivial images".) The "Daguerreomania" was now definitely on, to the delight both of those who profited by it and the others who would do so by lampooning it.

A New Industry. In the very first years of the daguerreotype era, among 20 camera artists operating in Hamburg, 13 used to be portrait painters and 2 lithographers. Of about 30 working in Berlin 16 used to be painters, 2 lithographers and 1 an engraver. Berlin, then a town of 300,000 inhabitants, cumulatively had 210 daguerreotypists established between the years 1839 and 1860. New York, then a city of 700,000, had in 1850 71 "daguerreotype galleries" employing 127 operators.

At the height of the daguerreotype business the best studio in Boston charged $5 (17s. 6d.; £3. 10s. today's value) for a large daguerreotype, but the standard price for a medium sized picture was $1. Towards the end of the boom prices slumped to 50, 25 and even 12½ cents. By that time the popular price in London was 1s. Richard Beard, a former coal merchant, is said to have amassed from his group of studios £40,000 (present value £160,000) during his first year of trading, the takings being sometimes £60 per day.

Some French daguerreotypists made 3,000 daguerreotypes per year. In 1849 the annual production of Paris amounted to 100,000 daguerrean pictures.

The commercial possibilities of what now would probably be termed "French postcards" were almost immediately discovered; pornography got itself attached to photography right from its tender youth.

But so has science. Astronomical photography, photomicrography, photogrammetry, stereoscopic photography and quite a few other fields of application were all approached in the daguerreotype era—just as Arago forecast that they should and would be.

But Louis Jacques Mandé Daguerre soon retired from the camera and to his painter's brush at the village of Bry-sur-Marne where he

died in 1851, leaving behind a scenic fresco in the local church. He himself may not have succeeded in doing much for the art of the camera, but he certainly established its trade.

THE TALBOT HERITAGE

Daguerre's influence was widespread and short lived; Talbot's impact was isolated but penetrating.

Curiously enough both inventors managed also to retard progress. Daguerre's enthusiasm unwittingly misdirected the technique of photography for nearly two decades. Talbot's stubbornness no less effectively blocked its logical immediate development.

Drawbacks. The main restrictive effect was, of course, created by Talbot's own decision not to permit free and general use of his invention. His personal disclosures of it were confined to scientific papers and expensive pictorial publications (*The Pencil of Nature* 1844; *Sun Pictures of Scotland* 1845). Popular instruction books comparable with Daguerre's literature did not exist; the best English manual of the calotype was published as late as 1855. Talbot obtained patents and appointed agents abroad. His agents in the United States do not seem to have succeeded in selling a single licence. His agent in France was ineffectual in preventing infringements. Talbot's process did not flourish except in Scotland, where it was not patented.

Then there were technical difficulties although Talbot had an organization comparable with Daguerre's for supplying equipment. Paper that served both for negatives and prints posed problems; its texture, and sometimes even its watermarks, would imprint themselves on to the picture. Not only the depth but also the colour would vary between light violet and strong sepia. Outlines and detail were not very sharp and often disappeared in over-exposed highlights and under-exposed shadows. The negatives had to be taken in the strongest possible sunlight that in its turn would produce excessive contrast. Exposures were several minutes long and could only be gauged properly by a great deal of experience.

Yet some of its limitations were to become the very source of the sporadic but lasting triumphs of Talbot's process.

The small and precise daguerreotype looked just "a mirror with a memory" (Oliver Wendell Holmes). Registering every minute detail, fold and blemish with uniform, documentary emphasis, daguerreotypes have a quaint charm—heightened by the elaborate frames and boxes in which they are encased. The daguerreotypist, who so often was a trained painter of miniatures, aimed at a compressed and digested record of likeness without frills; he did not grope for expression and rarely caught "soul". Daguerreotypes looked more standardized and manufactured than most later products of photography.

D. O. Hill. Inevitably the calotypist worked more on his own, had to experiment and rely on individual ideas. The most outstanding of them was a Scotsman, David Octavius Hill. Born 1802, the son of a Perth bookseller, he became a painter, took a busy part in Edinburgh's art life and acted as Secretary of the Scottish Academy of Painting, Sculpture and Architecture. He painted romantic landscapes and drew scenic illustrations for engravings on Scottish subjects; his work was competent but insignificant.

In 1843 Hill set out to commemorate the "Act of Separation and Deed of Demission" by the Free Church of Scotland. It took him twenty-three years to finish this canvas of 4 feet 11 ins. by 11 feet 4 ins. depicting 470 personalities. (He asked for a fee of £3,000 and was paid £1,500—about £6,000 in present value.) The artistic merits of this work are negligible: it is just a hand-painted "photomontage". The task of assembling such a number of individual likenesses in a single composition would have defied a much greater painter than Hill and in any case he had no experience in painting portraits. Besides, the problem of securing sketches of so many people seemed formidable. But he thought of a new way of getting them and it is these "sketches" that for ever engraved his name in the records of history.

Hill had been encouraged by the physicist, Sir David Brewster, to collect his sketches with the camera and to enlist the assistance of Robert Adamson, who had recently opened a studio in Edinburgh. Between 1843 and 1848 Hill and Adamson produced hundreds of camera portraits, not only of members of the Free Church Assembly but also of other outstanding personalities of Edinburgh's society. They also photographed genre scenes in Scottish harbours and took architectural and other scenes.

The portraits remain outstanding as a sublimation of the fertile eighteenth century English and Scottish painting traditions and their vigorous translation into a new medium. Lack of definition and limited latitude are virtues, not weaknesses, in the pictures as visualized probably by Hill and taken mostly by Adamson. Their subjects are presented in terms of carefully distributed contrasts of tone. What there is of detail seems deliberately picked for emphasis. The poses may have had to be chosen to sustain an exposure of up to three minutes, but each one of them sums up a personality, stresses a mode of life and hints at much that was valid about the sitter beyond the confines of a single exposure. It is almost uncanny. This new vehicle photography had barely emerged from nowhere and, steered by an obvious traditionalist, it was not only picking up a trail at once but clearly thrusting towards new horizons. A mediocre Scottish painter became both its revolutionary pioneer and its greatest classic.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Robert Adamson left Edinburgh in 1847 and died a few months later, only 27 years old. Hill gave up photography and when he took it up again in the 1860s with another collaborator it was with much less success. The portraits which he took with Adamson received an "honorable mention" at the Great Exhibition of 1851. But there is no reference to Hill in the notices about the foundation of the Photographic Society of Scotland five years later. When he died, 1870, his obituaries did not as much as mention his photography and photographic journals took no notice of his death. His opus was unearthed after twenty years, to be universally recognized as the prodigious achievement of a great artist who succeeded in exploiting all the depth of expression his unwieldy tools would yield.

Hill's achievement in all its curious singularity has a threefold significance. It gives Talbot's process a sort of raison d'être. It demonstrates the prowess of this infant prodigy called camera. It established an early precedence for what is going to happen in the history of photography over and over again, where outsiders, amateurs and other non-professionals so often break into commercial trends and redirect them towards new aims.

Blanquart-Evrard. Next to Hill's, the most important use made of the Calotype process was by Louis Désiré Blanquart-Evrard. He failed to acknowledge his indebtedness to Talbot, but quickly recognized the value of the process in producing illustrative work. He exposed the paper sandwiched between glass. He smoothed it by a coating of egg white and milk whey (albumen), used the gold chloride formula of the daguerreotype to produce reliable brown tones, introduced a better developer and speeded up the printing process. In 1851 he built a printing works at Lille where he employed 30 to 40 assistants and is reported to have produced hundreds of thousands of prints. His first publication was the folio *Egypte, Nubie, Palestine et Syrie*, containing 125 prints from paper negatives taken on a Mediterranean trip by Maxime du Camp accompanied by Gustave Flaubert. Blanquart-Evrard also published impressive prints of monumental architecture studies by Henri le Secq and Charles Negré.

He was the first professional photographic publisher and the first to grasp that the camera could show more to more people than any pair of human eyes could ever hope to see without its aid.

Significance. Within a very few years of its birth photography was established as a trade, tried as a tool of art, used as a new medium of communication and thrust from many directions into the realm of science. Soon it was to father cinematography, that in turn became television's parent.

Photography and its offspring presented new visions of the world to the world and by doing so changed it.

Man who since the Middle Ages had grown increasingly introvert was made newly aware of his environment. His eyes were re-opened. Habits of verbal abstraction are now checked by a new wealth of visual impacts. Thinking is interrupted by seeing. Speculation is faced with documentation. The image has become partner and rival to the word.

The visual message, being direct and understood by everybody, enormously widened the scope of spreading knowledge and pleasure. Pictures may not always show facts, but thoughts do not always arrive at truth either. The mean of visual attraction may be on a lower level than that of intellectual appeal, but it does lay out an incomparably broader social foundation on which future generations should be able to build a great deal higher.

And that fact by itself makes photography the most significant invention since the discovery of printing. A.K.-K.

DISDERI, ANDRÉ ADOLPHE EUGÈNE, 1819–90. French professional photographer and inventor. In 1864 produced a twin lens camera of which the upper lens was used as a finder only. Proposed use of photography for military purposes and drew up syllabus of instruction. In 1853 opened the largest studio in Paris and the following year introduced the photographic carte-de-visite which gave a tremendous stimulus to photography. Photographed many celebrities and published his photographs of celebrities from 1860 on. In 1861 was reputed to be the richest photographer in Europe. Opened branches in Toulon, Madrid, and London; died penniless, blind and deaf.

DISH DEVELOPMENT. Method of developing exposed sensitized materials by immersion in a shallow dish of the developing solution. This method enables the progress of development to be observed under a suitable safelight and controlled by adjustment of development time or sometimes the constitution of the developer.

See also: *Developing negatives; Developing prints.*

CC-0. Singh, Gurbir Singh Manmohan Digital Preservation Foundation, Chandigarh

DISHES. Processing dishes are used for processing single plates or sheet films. Prints are almost invariably processed in dishes.

The use of an open dish for negative development offers certain advantages over a tank. Development can be inspected under a suitable safelight. A relatively small quantity of solution is used and, after use, thrown away. Fresh solutions, uncontaminated by oxidation products, can thus be used for each negative. The solution can be kept moving to give even development. Rocking the dish is generally sufficient but, when quantitative measurements are to be made on the negative, as in photographic photometry or spectography, a brush can be used on the surface of the emulsion. For rapid processing at abnormally high temperatures, dishes are preferable since they can be readily heated, hold only relatively small volumes of solution and allow vigorous agitation during processing.

Dishes may be made of a variety of materials, the more common being xylonite, porcelain, plastic, enamelled steel and stainless steel.

Xylonite. This is one of the earlier types of moulded material used for making dishes. It has the great merit of being cheap and is reasonably resistant to processing chemicals. It does tend to stain, however, and the surface is not glass smooth and is somewhat difficult to clean. It is advisable to keep one particular dish for developer and another for fixer. The xylonite is usually of a fairly thin gauge and in the larger dishes it tends to buckle.

Porcelain. Porcelain was at one time the most popular material available for dishes principally because it is non-absorbent (at least when new) and has a glazed surface that is easy to clean and does not stain. On the other hand it is heavy and fragile and relatively expensive. After some time in use the glaze becomes covered with a fine network of cracks. When it reaches this stage it may absorb chemicals and cause staining.

Enamelled Steel. This is one of the most satisfactory of the cheaper materials available. It is as impervious to chemicals and as easy to clean as porcelain, but it is lighter and its surface does not tend to "crack" after a period of use. The one disadvantage of enamelled steel dishes is that the enamel chips off if the dish is knocked or dropped. Once the enamel is chipped off the inside of the dish, it exposes the metal to the action of the chemicals and the dish must be thrown away.

Plastics. Several types of plastics are now used for photographic dishes; they are generally cheap, light to handle, and easy to clean. According to the type of plastic used, they may be anything from tough and unbreakable to extremely fragile. As a rule, the harder the surface the more fragile the plastic, but some materials make up for their lack of surface hardness by being water-repellant and therefore stain-free and easy to clean.

Stainless Steel. This material is almost ideal from the functional angle, but it has the great drawback of being expensive. It is non-absorbent, easily cleaned, light in weight and virtually everlasting. While it is not affected by ordinary processing chemicals it may be attacked by some of the chemicals used for processing colour material.

Other Materials. In addition to the above, celluloid, ebonite, bakelite and glass have been used but have now been mostly superseded principally by enamelled steel and plastics. For very large prints it is customary to use shallow wooden trays, either lined with lead, or treated with acid-resisting paint or pitch.

Shapes. All processing dishes are rectangular and conform to the format of the ordinary negative and printing materials. Most—but not all—have a lip at one corner for pouring off the used solution. This lip is generally small, but on the more recent types of plastic dish there is a very generous lip.

The bottoms of dishes are shaped in some way to make it easy to insert a finger tip under the plate or print. Porcelain dishes usually have a depression at one corner and a groove along one side, but these are only effective with a plate or print that fills the dish. The best arrangement consists of two raised parallel ribs down the centre of the dish which hold the whole of the plate or print off the bottom even when it is very much smaller than the dish.

All dishes up to 8 × 10 ins. should be at least 1½ ins. (4 cm.) deep (and larger formats proportionately deeper) to prevent solutions from slopping over the edges. The sides should slope out slightly, and all the corners should be well rounded to make cleaning easy and to leave a gap to allow the edge of the material to be picked up.

Sizes. Most dishes of enamelled steel, plastics or stainless steel are available in a range of standard print sizes.

DISH SIZES

Ins.	*B.S. Size No.*	*cms.*
3¼ × 4¾	1	9 × 12
5⅛ × 7⅛	2	13 × 18
6½ × 8½	3	16·5 × 21·6
*7 × 23		17·7 × 58·4
8 × 10	4	20·3 × 25·4
10 × 12	5	25·4 × 30·5
12 × 15	6	30 × 40
14 × 17		35·6 × 43·2
16 × 20	7	40 × 50
20 × 24	8	50 × 60
30 × 40		76 × 100

*Especially for strip postcards.

The size of a dish denotes the largest standard material that the dish will accommodate. This allows a slight gap or margin to spare, but in practice it is always advisable to buy one size larger than the largest material to be processed. Also, since there will generally be

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

more plates or prints in the fixing dish than in the developing dish, the fixing dish should be the larger and deeper of the two. This distinction also makes it easy to tell one dish from the other in the darkroom.

If dishes of a sufficiently large size are not available and it is necessary to resort to see-saw processing, fairly deep dishes should at least be selected. G.B.M.

DISODIUM PHOSPHATE. Alkali used in developers, principally in fine grain formulæ.

See also: *Sodium phosphate, dibasic.*

DISPERSION. Materials which have a refractive index which varies according to the wavelength of the light—i.e., bend the rays of some colours more than others—are said to disperse light rays. A prism placed in the path of a ray of white light bends the blue and violet rays more than the orange and red, so that it spreads out or disperses the colours as a continuous spectrum.

All transparent materials show dispersion. A lens is usually made of glass and is chosen to

DISPERSION. A ray of white light entering a lens is split up into rays of its component colours, because the angle of refraction r for a given angle of incidence i varies with the wavelength of the light. This is the phenomenon of dispersion. The degree of dispersion depends on the type of glass the lens is made of, but not necessarily on its refractive index.

have a fairly high index of refraction to give it a high optical power for a shallow positive curvature. Unfortunately the unavoidable property of dispersion comes into the picture and the lens, instead of bringing the light rays to a point of sharp focus, spreads them out in a miniature spectrum. This effect is known as chromatic aberration; and designers of better quality lenses have to get rid of it by using more than one type of glass.

Glasses used by lens designers have to be made to very precise limits of refractive index and dispersion because the figure given by the manufacturer is the basis of the mathematical calculations used in designing the lens. R.B.M.

See also: *Aberrations of lenses; Lens.*

DISSOLVE. One of the most used transitions (next to the cut) from one scene to the next in a motion picture film. In a dissolve the second scene starts appearing faintly through the first scene at the beginning of the transition, then gets stronger and stronger while the first scene fades away. It can be produced in an amateur film by fading out one scene, winding the film back to the beginning of the fade in the camera, and then fading in the next scene. The superimposition of the fade-out and fade-in produce the dissolve. In professional motion pictures the dissolve is usually produced at the printing stage.

See also: *Cine technique.*

DISTANCE ESTIMATION. When a camera is focused by scale, the distance of the subject must be estimated or measured. One of the easiest ways of estimating the distance is to imagine how many times a 6 foot man could lie down flat between the camera and the subject. This method can become surprisingly accurate with practice.

The alternative is to measure or pace out the distance, taking the length of a comfortable stride as one yard.

It is useful to remember that an average person about 9 feet away just fills the longer side of the normal viewfinder. At 18 feet away he fills roughly half the finder, and so on. This is an approximate method, and the actual distances will vary a little with the camera used, and from finder to finder. So a few preliminary tests are advisable.

Where subject conditions make accurate estimation of the distance difficult (e.g., moving subjects) it is often better to use some zone focusing system, relying on depth of field.

See also: *Focusing rangefinders.*

DISTANCE GAUGE. Close-up accessory for certain cameras, especially miniatures, consisting of a rod or other fitting of fixed length which is attached to the camera and may carry a frame. When used in conjunction with specified supplementary lenses or extension tubes, the tip of the rod defines the exact camera-to-subject distance for a sharp image on the film. The frame outlines the field of view covered at that close-up distance. Alternatively the gauge may consist of a set of extendable legs, the tips of which define both the subject plane and the field.

See also: *Close-ups; Macrophotography.*

DISTORTION. The camera lens normally forms an image which is a faithful representation in scale and perspective of the various elements of the scene in front of it. Any alteration in the shape or proportions of the normal image at any stage of the photographic process is known as distortion.

Some types of distortion are beyond the control of the camera user. One of the principal off-axis aberrations of lenses produces distortion of the image formed in the camera. When a lens suffers from distortion it reproduces

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

straight lines away from the centre of the field as curves. Those lines whose middles curve inwards give what is known as pin-cushion distortion and those curving outwards barrel-distortion.

Other types of distortion can be deliberately produced by the photographer either for novel effects or to produce a more pleasing representation of the scene.

The use of a focal plane shutter when photographing fast moving subjects also gives rise to distortion, as different parts of the film are uncovered at different instants while the image changes in position.

Perspective distortion, which apparently exaggerates the relative proportions of objects close to the camera, is not in fact distortion; it is a true perspective image for the abnormally close viewpoint. This effect however is often used deliberately in such fields as, for example, architectural photography, for the sake of originality. Conversely the relative proportions of objects can be minimized by taking a more distant view-point and using a lens of longer focal length. This will still achieve the desired size of image on the negative.

See also: *Aberrations of lenses; Camera movements; Perspective; Shutter; Tricks.*

DISTORTION OF MATERIALS. Change in size of a photographic image due to expansion or shrinkage of the base support under the influence of temperature, relative humidity, processing or ageing.

See also: *Dimensional stability; Supports for emulsions.*

DIVERGING LENS. Lens which is thinner in the centre than at the edge. It has at least one concave surface. Rays of light passing through a diverging lens are refracted away from the optical axis. A diverging lens can only form a virtual image of the subject—i.e., one which cannot be focused on to a screen; it cannot form a real image as does a converging lens.

DOCUMENTARY PHOTOGRAPHY. At its lowest level, documentary photography is mere factual reporting, but in the hands of a master it can achieve the status of an art form.

Uses. Documentary photographs of the latter type are a popular feature in the illustrated magazines and even in the daily and weekly newspapers. Their principal value in this sphere is in bringing the reader a picture of the lives and customs of people normally outside his experience. Folk activities, peasant life, strange customs and crafts, are all a fruitful field for the documentary photographer.

At the same time, the famous documentary specialists find their material in less obvious and exotic quarters. These men are artists rather than globe-trotting reporters.

Documentary photography of this type has a very positive value in propaganda and education. Examples can be seen in the publications of political and religious groups, advertising literature and industrial house magazines.

Technique. Documentary photography is practised with all types of equipment from 8 × 10 ins. cameras down to sub-miniatures.

The aim is always to produce unselfconscious pictures, and most workers favour an unobtrusive camera and candid approach. Even so, some world-famous specialists use large stand cameras and achieve the unposed effect by skilful handling of the subject.

There is thus no established documentary technique; it is simply a matter of applying the principles of normal photography directed by the vision of the artist—or at least, the eye of the reporter. Inevitably the result is coloured by the personality of the photographer and a practised eye can recognize the style of any one of a dozen leading specialists.

Most documentary photographers, however, assume or affect an emphatically plain approach avoiding pictorial conventions, and suggesting that the subject matter has undisputed priority.

The Cine Documentary. While a documentary work may be no more than a single print, it is more often a series of prints, since it deals with life and movement. For the same reason that several prints are generally better than one, a cine film is better than a series of stills. The documentary film has in fact reached a high state of perfection in recent years. Public interest in this type of film is high; so much so that a number of documentary films have unexpectedly scored major successes in terms of the actual box office receipts.

DOCUMENT COPYING

Photographic document copying is a method of making a factual copy, normally on paper, of an existing original or copy document. This can be printed, handwritten or drawn and may contain illustrations, both photographic (continuous tone) or reproductions (half-tone), or diagrams in monochrome and colour. There are various processes of document photography to copy such documents. Some have limitations and may not be able to deal adequately with all originals, especially those containing both illustrations and text, and some are unable to reproduce certain colours. As a general rule, these processes copy by contact printing and therefore produce same-size copies, but a few use optical methods and some can vary the size of the copy from that of the original.

The photo-copying methods belonging to the drawing office techniques (often called plan

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

copying) are blue print (ferro-prussiate), diazo and true-to-scale (T.T.S.) and all these will print from a translucent master. Such masters are normally prepared by draughtsmen or tracers, but numerous methods of making them from opaque originals are also available. But most of the other document copying methods can make copies from opaque or double-sided originals and some do so directly, without making a negative intermediate.

PROCESSES

All these methods can be classified into five categories, namely:

(1) Plan copying, as previously outlined.
(2) Silver processes, which include negative-positive, reflex and direct positive processes.
(3) Transfer methods (diffusion and gelatin).
(4) Thermographic (heat) systems.
(5) Electro-photographic processes.

Blue Prints. The most familiar process is that commonly used for copying architects' and engineers' drawings and plans to give facsimile copies—i.e., copies of the same size as the original. An accurate tracing of the drawing is first made on a transparent or translucent paper or tissue. This is then placed on a sheet of sensitized paper with its back to the emulsion, and held in close contact with it by pressure. The sensitized paper is then exposed to light through the tracing and it receives an impression which may be visible and needs only to be fixed, or it may have to be developed. This depends upon the type of sensitized material used in the particular process.

In its simplest form, this process, known as the blue-print, cyanotype, or ferroprussiate process, was discovered by Sir John Herschel in 1842. It depends upon the fact that when light acts on certain sensitive ferric or iron salts, it can reduce them from the ferric to the ferrous state. In the well-known blue-print process the action of the light turns the treated paper blue, while the parts shaded from the action of the light by the lines of the drawing remain white. When the blue print is deep enough the whole print is well washed in water. This dissolves and washes away the unused ferric salt and fixes the image.

The blue print process uses ferro-prussiate paper, which is of low sensitivity and so is exposed in a photo-printing machine having a powerful light source. By using a translucent intermediate negative master, a positive copy having blue lines on a white ground is obtained and special chemicals can be used to strengthen the density of the blue image. The blue print is sometimes preferred by engineers because it will stand rough handling in the workshop, but generally the method is being superseded by diazo type. The ferro-gallate or black-line process giving blue-black lines on a white ground, was also used for some time.

Diazotype (Dyeline). Diazo paper uses a diazo type instead of iron salts and is exposed in the same type of apparatus. Being a positive method, it will produce directly from the normal translucent master a positive copy which could be one of many available tones. There are three types of material which differ in the method of development (coupling) and are generally described as semi-dry, ammonia or heat.

DIAZO PROCESS. The original for diazo duplication is printed, typed etc. on translucent paper. Light passing through this decomposes the diazo compound in the diazo paper. The unexposed compound is then coupled (developed) to form a dye image. This can be done in a solution, by ammonia vapour or by heated rollers. A, original. B, diazo paper. C, direct copy (positive-positive) after coupling.

The semi-dry type is coupled with a single solution developer containing ammonia but emerges from the machine in a dryish state. The dry types are processed by exposure to ammonia vapour or heat. The necessity of extracting the ammonia fumes from the vapour is a small disadvantage, but the heat method is mobile although there is a tendency at present with this type to emit faint but unpleasant odours.

Diazo is extensively used in administrative offices for making carbon copies and for systems work. Small machines of elegant design have been introduced for this purpose, together with special translucent typing papers and diazo material of much better quality, which is able to produce a copy of good density. Because this material can be operated in daylight, is simple to use and is the cheapest form of sensitized material available, it has many advantages.

Lithographic Systems. The true-to-scale (T.T.S.) method requires more operational skill because it can be affected by temperature and humidity changes. In principle it is lithographic and is based on the premise that grease and water will not mix. The apparatus consists of three rollers which hold a continuous belt of linoleum and this is coated with an emulsion prepared by heating and known as the plate. When set, this emulsion receives an image from exposed but undeveloped ferro-prussiate paper, the image being inked and transferred manually to a receiving base which can be translucent, opaque, card or paper. The quality of the copy produced is of a high order and it is therefore a good method of making intermediates for diazo or other processes. The term "true-to-scale" is, however, a misnomer and should not be taken too literally.

CC-0. Jagmohan Singh Digital Preservation Foundation, Chandigarh

A lithographic system is used in most office offset litho machines. These are printing presses, and photography enters only into the production of the litho master that provides the printing surface. Such masters are made by transfer-diffusion or electro-photographic methods (see below) using specially prepared materials. The main advantage of office offset methods is their cheapness and high output when large numbers of copies are required from one original.

Silver Processes. Most negative-positive processes, whether contact printing or photography in a copying camera, work on the same principle as normal negative-positive black-and-white photography. They thus involve the production of a negative and the printing of a positive. The negatives may be made on high-contrast films or plates (usually in a camera) or document papers (in a camera or a contact printer). This negative is then printed (usually by contact) on to a document paper to yield the positive. The negative and positive go through the usual processing stages of development, fixing and washing, followed by drying.

These processing stages tend to be lengthy and tedious, so modern negative-positive document processes frequently use rapid processing papers that incorporate the developing agent in the emulsion. Such papers are suitable for roller processing in developing machines; the paper there passes between a set of usually motor-driven rollers that apply a film of activator solution to the paper surface. This develops up the image within a few seconds. The paper then moves through a stabilizing bath and through a pair of squeegee rollers to emerge as a semi-dry print. Frequently the same paper is used for making the negative and the positive. Special papers are also available which give good copies from continuous-tone photographs and from normal photographic film negatives (also continuous-tone) in a fraction of the time required by traditional methods.

Self-positive papers use pre-fogged silver halide emulsions that give a positive copy by direct exposure. The exposure destroys the latent image fog by solarization or by the Herschel effect (if the exposure is carried out by orange, yellow or red light) so that the exposed portions remain white while the unexposed portions develop up black. Self-positive papers are usually processed by a development and stabilization technique.

Transfer Methods. These first make a negative from which a positive copy is transferred (without exposure) to a specially prepared paper.

The commonest method, diffusion transfer, uses a silver halide system. A sensitive negative paper is exposed to the original document, and processed in contact with a non-sensitive positive paper. As the negative image develops in the negative paper, the unexposed silver salts diffuse into the positive layer and are reduced by chemical fogging to a positive silver image. Normally transfer-diffusion yields one positive per working cycle (exposure of the negative and processing of the negative and positive papers). Several positive copies can be made from special negative materials by repeating the processing stage. The positive can also be on film (for making translucent masters for diazo copying), on metal plates for offset lithography, or on special materials to yield carbon masters for hectographic (spirit printing) duplicating processes.

DIFFUSION TRANSFER. The negative is exposed by reflex copying and then passed in contact with a positive sheet through a developing solution. The unexposed sensitive compounds in the negative diffuse into the positive and there form a silver image. A, original. B, undeveloped negative. C, positive. D, negative during development.

Dye transfer uses a special emulsion which contains a dye, sensitive silver salts and developing chemicals. On activation in the processing solution these develop the silver salts, couple the dye and tan or harden the gelatin. In the

DYE TRANSFER. This uses a matrix with a gelatine coated surface which contains a dye and a mixture which can be activated to develop the exposed silver salts, couple the dye and tan or harden the gelatine. The matrix is exposed by reflection and after controlled development pressed against a positive paper. This picks up a thin layer of unhardened dyed gelatine from the unexposed areas, thus producing a positive image from a positive. A matrix may produce up to six copies by repeated transfer. A, original. B, matrix. C, copy. D, activated matrix.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

resulting matrix exposed areas are hardened gelatin and the unexposed portions soft gelatin that can be transferred. After development the matrix is pressed against the positive paper which picks up a thin layer of unhardened dyed gelatin from the unexposed areas, thus producing a positive image. One matrix can give about six copies; the transfer is made in quick succession and so is cheap operationally.

As all transfer methods involve a lateral reversal of the image, they are usually employed with reflex printing methods where the negative image is reversed left to right at the exposure stage. Specially sensitive dye transfer papers also exist for exposure in a camera at an enlarged or reduced scale. These can also be used for making printing masters for offset lithography.

Thermographic Systems. These involve exposure by infra-red radiation, use no liquid chemicals, and produce instant dry copies. For a thermographic copy a heat-sensitive paper is exposed, by the reflex method, in contact with the original to be copied. The heat rays reflected

HEAT COPYING. The paper contains a heat sensitive compound and is backed up by the original. This sandwich is exposed to an infra-red source. The infra-red rays are absorbed by the carbon or metallic part of the image; the reflected heat forms an image on tho copy paper. A, heat sensitive paper. B, original reflecting heat and thus forming a positive copy from a positive original.

by the dark portions (text, etc.) of the original darken the thermographic paper, producing a positive image. To obtain a right-reading copy, the thermographic paper is exposed with its back in contact with the original; as a result the image is usually slightly unsharp. This process takes a few seconds, and is thus particularly suitable for automatic office copying machines which require no attention beyond feeding the original and the heat-sensitive paper through the unit.

An alternative system uses a carbon paper which is softened by heat and then transfers an image from the original on to normal paper. Another process uses a black paper with an opaque white coating. The heat melts this coating, allowing the black ground to show through as an image.

Since all heat processes depend on the reflection of infra-red radiation, they work only with originals printed or written in inorganic pigment inks. This covers typewritten and printed document material, but not originals written or printed in dye inks.

Electro-photographic Processes. These rely on the image-wise discharge of an electrically charged surface on exposure to light. The surface then carries an electrostatic image.

In xerography, the electrostatic image on a selenium coated plate is made visible by dusting with charged pigment particles. The pigment image is then transferred to ordinary paper and fused into the paper by heat treatment. This system is inexpensive to run, since the copies are made on ordinary paper; the equipment, however, is expensive.

A second system forms the electrostatic image on a zinc oxide coated paper which is then dusted with pigment powder and the latter fused into it.

Electrophotographic methods are not suitable for contact printing, since the electrostatic image would be destroyed on contact with another surface. The image must therefore be projected on to the plate or paper in a special camera, but copies can be made on any enlarged or reduced scale. Electro-photography is therefore used for re-enlarging microfilm negatives or positives. By appropriate choice of the electric charge of the plate and of the pigment powder, the process can yield a positive from a negative or a positive from a positive.

Electro-photographic methods are versatile because they can produce, in addition to document copies, masters for the diazo, hectographic and lithographic processes. They do not easily copy solid areas and for this reason are less suitable for continuous tone copying. New materials have improved these weaknesses, but further progress is still desirable.

Costing. The comparative costs of document copying methods depend on the actual cost of the material used for making the copy as well as on the investment in the equipment required and the efficiency and speed with which copies can be produced.

Material costs are lowest with the processes that produce the final copies on ordinary paper—offset litho and xerography. Offset litho is also capable of producing copies at a very fast rate, but requires a photographic litho master. Where many copies are required, the cost of the master per copy becomes negligible.

Xerography is rather slower since every copy requires a complete cycle of exposure, pigment processing, transfer and heat fusion. The high cost of equipment and operating time is balanced only by the extra versatility of the process; for mass output, xerography is primarily useful as a means of producing masters for the other processes. Automatic continuous flow xerography, utilizing a selenium drum, can appreciably speed up the operating cycle but needs even more expensive gear.

Plan copying methods, especially dyeline, use the cheapest sensitized material for the final copy. They are thus economical for a

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

ELECTRO-PHOTOGRAPHIC COPYING. The original is optically projected on to a charged surface (selenium-coated metal or paper coated with resin and zinc oxide). Reflected light from the non-image areas of the original dissipate the charge, allowing an oppositely charged powder to adhere to the charged areas. The powder is fused on to the paper or transferred from the selenium to the paper and fused there. A, original. B, charged paper or metal surface. C, fused image copy. This yields a positive from a positive.

reasonable volume of multiple copies where the acquisition of offset litho machinery is not possible or desirable. Dyeline printing also requires a master—made photographically on translucent paper or film—and the speed of operation depends largely on the complexity of the exposing and processing machinery.

Thermographic processes are slightly more costly per copy (and the print cost is independent of the number of copies) but attractive for their simplicity.

Negative-positive (and direct positive) silver processes cost still more per copy, since the document paper is more expensive. For single copies they are comparatively slow, since—with negative-positive printing—both a negative and a positive must be made. One negative can however give any number of positives at a constant cost.

Transfer methods are slightly quicker for single copies since the final print is made in one stage. For a few copies, up to half a dozen, multiple transfer materials are suitable; for single copies and for high quality multiple copies, transfer processes are more expensive since every copy requires a negative and a positive sheet of paper.

TECHNIQUES

In office copying systems, prints are usually made by contact printing or reflex copying. This yields copies of the same size as the original. Where enlarged or reduced copies are required, the original must be re-photographed in a camera.

Contact Printing. Translucent originals, for example letters written on one side of the paper only, can be copied by transmitted light. This is suitable for silver and dyeline processes, and yields a negative or positive in one stage. If only a negative is required for reading, or with processes yielding a direct positive copy (self-positive papers, thermographic systems, etc.), the original must be placed with its back in contact with the sensitive surface of the copying material in order to yield a right-reading print. If the negative is used only in the intermediate stage for positive copies, the sensitive layer of the negative paper can be in contact with the image surface of the original.

Contact Printing from Tracings. In the modern drawing offices special printing machines are used for making prints from master tracings. These machines incorporate a stand supporting a hollow glass cylinder in which a fluorescent tube is mounted. The cylinder is turned slowly by an electric motor and at the same time the carbon arc travels continuously to and fro between the ends of the cylinder. The tracing and a sheet of blue or black line printing paper are wrapped around the cylinder and held in close contact by an outer covering of tightly stretched fine-wove canvas. The traversing speed of the tube can be adjusted to give exposures from 20 seconds to about 1½ minutes.

In large offices a modern printing unit, takes the print through automatically, developing it with ammonia vapour and delivering the finished copy ready for use. These machines are very economical where large numbers of prints are required.

Reflex Copying. This method makes use of the light reflected back from the surface of the document instead of the light passing through it. The document to be copied is laid face upward on a flat surface and covered with thin bromide paper or a sheet of special reflex document paper, emulsion face down. A sheet of plate glass is used to apply pressure to keep the two in close contact. Light is then allowed to pass through the back of the sensitive paper. This light is the same all over the copying paper, but more light is reflected back from the white paper of the document than from the dark print. So the copying paper in contact with the lighter parts of the document gets an extra dose of light—just enough to make it turn black on development while the printed parts remain white.

REFLEX COPYING. Light from above passes through a glass sheet and then through the sensitive paper laid emulsion side down on the document to be copied. Dark areas of the document (writing) absorb the light, white ones reflect it back on the emulsion, and thus produce a negative reversed image. Re-copying by the same process produces a positive.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Exposures are in the region of 5 to 25 seconds, the exact time being determined by making test exposures. The development, fixing, and washing of the print are carried out just as for a bromide print, and the final result is a negative of the document. Any number of positive prints can be made from this negative by contact printing in the usual way, through the negative on to a sheet of bromide paper.

Reflex copying is used both with negative-positive silver processes (usually employing special rapid processing papers with incorporated developing agent) and with transfer processes. Reflex copying is virtually the only contact printing system suitable for transfer materials since the image is reversed left-to-right during transfer and so needs the already reversed image produced by the reflex process. The same double reversal takes place in making the negative and from it the positive in the negative-positive process. Self-positive papers are not suitable for reflex copying since no second reversal of the image can take place.

Scale Copies. There are many cases in which it is important to have scale copies either larger than, equal in size to, or smaller than the original. Facsimile copies by reflex printing of very large plans would be unnecessarily bulky and expensive, while small documents are made much easier to read and handle if they are enlarged. Copies of this sort can be made in any type of camera from a miniature upwards, but half or whole plate sizes are generally used because they give usable prints direct from the negative without further enlargement.

The copying camera may be mounted vertically or horizontally and must have ample extension and a lens with a perfectly flat field and high resolution. Ordinary photographic films and plates may be used, but paper-based emulsions are more usual because they are cheaper and easier to store. These document papers are supplied in a wide range of thicknesses and emulsion speeds on either opaque or translucent paper bases.

A special stripping paper is also manufactured from which the hardened gelatin coating is stripped away after it has been exposed and processed. The resulting transparent negative can then be used for printing off any number of positives or it may be read as a positive through the back of the gelatin.

Camera copying is suitable for both negative-positive and transfer systems. When document papers are used for the negative, the positives are then produced by contact printing. Transfer materials need intense lighting of the original, since their speed is usually rather low. Camera copying is also the only way of making duplicates by electro-photographic processes.

For casual copying of originals of various sizes, reduced-scale film negatives can be made in an ordinary camera with appropriate close-up accessories; these negatives are then re-enlarged either to original or to a smaller size.

Microfilming. This is a special application of camera copying and involves reducing originals on to 35 mm. or 16 mm. film for particularly compact storage. The information from microfilm negatives is usually extracted by viewing in suitable viewers which project a magnified image on a screen. Microfilm negatives may also be enlarged on document papers when full size copies are required for reference or distribution.

Continuous-tone Originals. Most document copying materials yield an image of extreme contrast and are thus primarily suitable for reproducing text and line illustrations. Half-tone images—i.e. reproductions of photographs broken up into larger or smaller black dots as in a newspaper or book—can be copied in the same way but usually require shorter exposures to prevent the dot pattern of the image from blocking up. The copying material in this case must have a higher resolving power and—in contact copying—the original and copying paper must be in very intimate contact to reproduce the dots sharply.

Continuous-tone originals, such as photographic prints, are usually copied in a camera on to a soft working film (or plate). Duplicates can then be made by contact printing or enlarging the film on to a medium- or high-contrast bromide paper.

This is generally possible only with silver negative-positive systems. Continuous tone originals can be reproduced by transfer, dyeline and electro-photographic methods if they are first converted into a half-tone image. This involves making, for instance, a dyeline master on film by photographing the original with a half-tone contact screen in contact with the photographic film. A positive transparency made from this half-tone negative can then serve as the dyeline master. For electro-photographic reproduction the half-tone negative itself can be projected on to the xerographic plate or electro-photographic paper. Equally such a negative can be printed by contact or enlargement on to a high-contrast document paper for any number of positive half-tone prints.

With transfer processes, especially diffusion transfer papers, the half-tone negative is made by photographing the original in a copying camera, with the half-tone screen in contact with the negative paper. This is then processed in the usual way in contact with a positive paper to yield a positive half-tone print.

Half-tone contact screens are not suitable for contact printing processes, since the screen must separate the original from the sensitive material; hence this involves some loss of detail. Equally, half-tone screens are not suitable for reflex printing.

Special Techniques. The application of document photographing principles to stencil and jig making has been of the utmost value in speeding up production and shortening the

several procedures that intervene between the drawing office and planning and layout lofts in aircraft and marine engineering where large and costly templates, jigs, patterns, and stencils are used.

By an extension of the methods of document photography it has been possible to project on to sheet metal, plastic or other appropriate material the images, in exact scale, of the forms into which the material has to be cut. This method of marking off the work for machining does away with templates by printing or projecting an absolutely accurate photographic scale image on to the actual material to be used.

Originals that have become faded, stained, or even completely bleached or obliterated can often be rescued by photographic reproduction. The particular technique used depends upon the condition of the original.

Where the document or its contents are coloured, it is normal practice to increase the contrast of the final copy by using a panchromatic plate and a suitable filter. For coloured script, a panchromatic plate and a filter of the complementary colour are used to darken the tone of the script. For coloured paper, a filter of the same colour as the paper is used to make the paper reproduce in lighter tones.

It follows that for old documents where the script has faded and is yellow or brown but the background is reasonably white, an ordinary or panchromatic film with a blue filter will restore the contrast by darkening the tone of the script. Where the document itself has yellowed and gone darker, a high contrast panchromatic film with a deep yellow filter will give the necessary contrast by lightening the tones of the paper.

When blue prints have to be copied, panchromatic films or plates are used with a tricolour red filter to make the blue of the print come out black in the photograph. For Photostat paper which is a fairly deep yellow, a deep yellow filter is used to make the ground come out white.

Phototelegraphy. Phototelegraphy is another direct development of document photography. Here, the document is wrapped around a cylinder which rotates while a beam of light scans it from end to end. A photo-electric cell picks up the light reflected from each minute area of the document in turn, and changes it into electrical energy which can be sent along a wire or transmitted by radio. At the receiving end, the electrical impulses are used to control the strength of a similar beam of light traversing a sheet of sensitized paper mounted on a cylinder rotating in synchronism with the sending apparatus. The result is an image that can be developed out to a very fair copy of the original picture. Photographs transmitted in this way are often used in newspapers.

Illumination. In commercial copying equipment the lighting unit or units is an integral part of the apparatus. It is always designed to provide even illumination over the whole area to be photographed, and the light is designed to give a correctly exposed negative with the standard setting of lens, image distance and illumination. Some adjustment is possible, but it is generally better to stick to a standard setting and standard conditions.

In much of the commercial apparatus auto-

CC-0. Agamirgam Digital Preservation Foundation, Chandigarh

matically controlled Photoflood lighting is used, the full power of the lights being on only during the actual period of exposure. As a general guide for work in a darkroom, four 100-watt lamps in reflectors at four corners of the table or support and 2 feet away from the surface upon which the document will rest should be adequate for ordinary copying. With fast panchromatic film or equivalent material and a lens aperture of *f* 11, the exposure will be about ¼ second. For micro-negative film the exposure will be about 2 seconds.

Copying equipment working with dyeline or other low-speed materials sometimes uses high-intensity mercury vapour lamps.

Special Lighting. Often there is no combination of film and filter that will make the written or printed matter stand out from its background when it is illuminated by the normal type of day or artificial lighting. When this happens, special forms of lighting like infra-red and ultra-violet will often give the right answer.

Infra-red light has been used successfully in photographing ancient manuscripts on leather and hide. It has also been successful in photographing charred and burned documents, in deciphering writing and printing obliterated by a censor, and in revealing the presence of chemically bleached writing on cheques, stock certificates and similar documents.

To find out if a document can be improved by infra-red light photography, it is first looked at through a deep red filter such as tricolor red. True infra-red filters are used for taking the actual photograph; they are useless for visual inspection. Infra-red negative stock must of course be used in the camera.

Ultra-violet light causes many inks and papers to fluoresce to a greater or less extent. This often makes it possible to photograph matter that has either completely faded or been intentionally bleached out or obliterated. The source of ultra-violet light is usually a quartz mercury vapour lamp used in conjunction with a filter known as a Wood's Glass filter which transmits only ultra-violet light and holds back all visible light.

The document is set up in front of the camera and photographed in complete darkness under the ultra-violet light. In this case there is no need for special negative material because the normal panchromatic plate is sensitive to the fluorescent light given off by the paper or script under this type of lighting.

Ultra-violet light has been used to reveal alterations on documents—forged dates, signatures, and the like—and for detecting the presence of otherwise invisible finger prints.

Sensitized Materials. There is quite a range of sensitized materials used in document photography. Plates, as a general rule, are not used.

For camera copying, the usual material is a contrasty process film, made in a variety of types and sizes by all main manufacturers of sensitive materials. They are further available in normal, fast, high-speed, and blue-sensitive, orthochromatic or panchromatic.

Films for micro-copying (microfilming) are supplied in widths from 16 to 105 mm.; the gauges from 16 to 70 mm. may be perforated. Papers for copying cameras are supplied in rolls or sheets. Appropriate materials are supplied by the sponsors of the various special office copying systems such as diffusion, dyeline, electro-photography, etc.

The speed of particular types of material may vary with individual manufacturers; with equipment that is not precalibrated for automatic exposure, it is advisable to determine the correct exposure by actual tests on the sensitized material to be used.

EQUIPMENT

The apparatus used for document copying must on the one hand be able to handle the materials for a particular process, and on the other cope with a range of originals of different types. Since much of this equipment is used in offices by people not trained in photographic procedures, a certain degree of automation is also desirable to ensure correct exposure and processing of the document copying material.

For small-scale use there are two main types of copying equipment: flat-bed and rotary printers.

Flat Bed Systems. The basis of a flat bed copy-

REFLEX OFFICE COPIER. Top: The unit normally incorporates an exposing light box with built-in lamps and timer, plus a motor-driven roller processing unit. Bottom: The processing unit consists of the solution troughs for transfer diffusion or (as shown here) development and stabilization. A, lid. B, pressure plate. C, opal glass covering light box (the document paper and original are placed on this). D, delivery slot of processor. E, stabilizing bath. F, developing (activator) bath. G, timer. H, feed-in slot. J, squeegee rollers. K, drive motor. L, developing rollers.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ing unit is a printing-box with a number of lamps underneath a diffusing screen to illuminate evenly the full area of the document being copied. A lid lined with sponge rubber or foam plastic (or sometimes with a spring-loaded pressure plate) presses the original and document material into intimate contact.

The printing box may incorporate a mechanical or electronic timer connected to the lamps. Since the illumination is constant, the required exposure for any given process depends mainly on the sensitivity of the copying material; once this is determined for average originals, it only needs slight variation for different types of original. With two-stage copying processes, for example negative-positive, the two stages may require different exposures. On some copying machines these can be selected by push button controls once a basic exposure has been set.

Modern flat bed copiers for development and diffusion-transfer materials are frequently combined with a roller processing machine for the papers. This is motor driven and carries the paper through the processing solutions at a rate which ensures full development. The transport system for negative-positive processes differs from that for diffusion transfer materials, since the latter use only a single processing solution. In transfer processing machines the negative and positive papers are fed into the developing solution through separate slots which keep them apart until they are seized by the rollers and pressed into contact (once the emulsion layers are saturated with the developer solution). Usually the machine has three such slots to permit two negative sheets to be pressed into contact simultaneously with the two sides of a double-sided positive.

Roller processing units are also available separately for negative-positive and transfer systems.

Flat bed copiers are made in a number of sizes from about 8½ × 13 ins. (foolscap) to 16 × 20 ins. or even larger. The flat bed copier is suitable for single sheet originals (e.g. letters) as well as for copying from periodicals and even books. Flat bed copiers for the dye transfer processes are similar in principle but have appropriately different arrangements for processing the material.

Some flat bed printers, especially those intended for making offset litho and other printing masters, have a vacuum unit to ensure absolutely perfect contact between the original and the copying material.

Rotary Copiers. These are more automatic than the flat bed machines and are suitable only for single sheet originals. The original and the copying paper is here fed into the machine past an exposure light (usually a strip lamp) or around an illuminated translucent drum. In either case the speed with which the material passes through the exposure station determines the actual exposure. This is matched to the sensitivity of the material used, but may with some machines be adjustable. After exposure the original and document paper are returned to the operator who then feeds the document paper through a motorized processing section. With some machines this is completely automatic and the machine itself delivers the original and the finished copy through separate outlets.

The rotary copier exists in various modifications for specific processes; for instance thermographic machines have an infra-red source for the exposure and no processing section.

Inexpensive contact printers may press the original and copying material into contact around the surface of a translucent plastic half cylinder containing the exposing lamps. This again is suitable only for single sheet originals, and the papers are pressed together with the aid of a flexible and spring tensioned apron. Such printers are slower to work, but suitable for more casual copying work.

Dyeline Machines. Small printers for diazo processes differ from negative-positive and transfer copiers in the light source (usually a mercury-vapour lamp since the dyeline paper is most sensitive in the ultra-violet spectral region) and in the processing arrangements. These may subject the paper to liquid treatment (to an ammonia solution—though some current materials are developed in liquids with a less objectionable smell), to ammonia gas or to heat. The exposure and processing sections may be separate, or combined into one unit.

Large dyeline printers used in drawing offices may handle papers up to 70 ins. wide. They consist of what is in effect a scaled up printing frame to take the original (usually a tracing or translucent master) and the dyeline paper. Exposure is to an ultra-violet source, after which the dyeline paper is processed.

COPYING CAMERA. This is a large camera which holds paper in rolls up to 18 ins. wide and 350 ft long. The original is photographed via a mirror and lens system which produces a negative tonal copy on processing, which is quite correct reading. The developing and fixing trays are fitted to the rear of the camera, the paper being moved directly to the developer and transferred manually to the fixing bath. Washing and drying apparatus are quite separate. A, paper holder. B, processing trays. C, mirror and lens. D, copy holder.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Duplicating Machines. Hectographic, spirit printing and offset litho-units are not photographic in operation, though they may use a photographic process for obtaining the printing master. The range is very wide and the machines vary in size and price according to the required output and format of duplicates.

Camera Copying. Large scale copying cameras can produce negatives or positives on any enlarged or reduced scale. A type of camera in use for many years—though now largely superseded by smaller and more convenient apparatus—takes the document paper in continuous rolls up to 350 feet long and 14 ins. wide. The paper is fed through the focal plane of the camera and cut off after every exposure. The sheet then passes through processing trays holding the developer and fixing bath. Such cameras are comparatively bulky and are often mounted on horizontal pedestals, photographing downwards on to a copy holder via a mirror or prism. This also reverses the image left to right, to yield a right-reading negative which can be used as it stands or contact printed to produce positive copies.

More modern document copying cameras frequently use a vertical layout, photographing downwards on to an easel with lights arranged to each side of it. The set-up is in effect an inverted vertical enlarger. The document copying material is placed in the top of a camera and may be held flat by a simple pressure plate or a vacuum board. Cameras of this kind are suitable both for making negatives by the normal negative-positive process and for exposure of the negative sheet of a transfer diffusion material. In the latter case no reversing mirror is needed, since a left-to-right reversal of the image takes place on transfer to the positive.

Special camera systems are also used for the electro-photographic processes, the camera being loaded with the selenium plate on which the electrostatic image is formed. The camera equipment there includes the apparatus for charging the plate and for dusting on the pigment powder and transfer to the final paper support.

Optical systems are also used for re-enlarging micro film negatives on to various types of document paper or on to sensitized material for forming masters for duplicating processes (offset litho, dyeline, etc.).

Continuous Flow Systems. These are fairly complex machines for the photographic production of large numbers of copies at comparatively low cost. They use electro-photographic and diazo systems.

Electro-photographic continuous flow machines work on the xerographic principle but with a selenium coated drum instead of a flat plate. The charging, exposure, powder processing, transfer and heat fusing stages are disposed around the circumference of the drum. The latter rotates continuously; the image is projected on the drum surface—at the exposure station—while the optical system scans the original document. At the end of the cycle the machine delivers the finished copy. The cycle can be repeated indefinitely for any number of copies at a rate of about four to six a minute. More advanced models may feed the paper in from continuous rolls and deliver copies at a paper web speed of up to 20 feet per minute.

CONTINUOUS-FLOW XEROGRAPHY. The documents are fed continuously through the xerographic printer, the image being projected on to a rotating selenium drum. Various points of the latter carry the charging, exposing and powder processing stages. The powder image is then transferred on to a continuously moving paper web and passes through a heating stage to fuse the image on the paper. A, mirror. B, optical system. C, lighting. D, document on feed unit. E, heating stage. F, paper take-up. G, charging point of selenium drum K. H, exposing station. J, powder processing. L, transfer to paper. M, paper web feed.

Continuous flow diazo units also use rolls of dyeline paper. Here the original is fed into the machine which takes it, in contact with the dyeline paper, round an exposing drum (a translucent drum containing the exposure lights), after which the paper runs on into a development section (liquid or vapour or heat) while the original is returned to the operator. The machine may incorporate trimming equipment to deliver ready stacked sheets of copies. Where large numbers of copies of one document are required, the latter may be attached to the exposing drum. Where a number of documents are to be copied on a one-off basis, the originals are continuously fed into the machine. H.W.G., L.A.M. & H.R.V.

DODGING. Term applied to local printing control by shading and spot printing. The technique is mostly used in enlarging.

See also: *Enlarging*.

DOEBEREINER, JOHANN WOLFGANG, 1780–1849. German professor of chemistry and pioneer photo-chemist. He discovered many photo-chemical reactions, including the sensitivity to light of platinum salts, tincture of iodine, ferric and manganic oxalates. Discovered the catalysing effect of finely-divided platinum, and above all, the light sensitivity of ferric oxalate, upon which such processes as cyanotype, platinum printing and other processes depend.

DOGS AND PUPPIES. Some dogs take no notice of the camera; but others are interested in the strange object and must be allowed to sniff over the equipment and satisfy their curiosity before they are willing to co-operate. (It is advisable to leave the lens cap on to prevent the lens from being smudged by a wet nose or tongue.)

Handling. Dogs which have been over-petted are generally difficult subjects because they take little notice of commands to keep still, beg, etc.

It is always unwise to try to manage the animal and take the photograph too. The handling should be left to a helper who has been told in advance what sort of picture is required. The owner is not always the best person for this because the dog is apt to concentrate too much attention on him. The average dog can generally be relied upon for a certain amount of co-operation if treated sympathetically.

The Best Time. Just before his regular meal-time a dog is alert and willing to do everything he can to help if he knows that he will be rewarded with a tit-bit. After his meal, he will be less anxious to please, but he will also be less fidgety. Each time has its advantages and will result in pictures of quite a different character.

But the important thing is to let the dog please himself; no attempt should be made to force or threaten him or the resulting picture will be a sorry affair. If he cannot be tempted with a reward and refuses to respond to a normal command, he should be left for a time.

Setting. There must be complete freedom to shift the camera position, so it is better to work out-of-doors. If the dog is allowed to find a favourite spot in the garden, he is less likely to wander off than in strange surroundings. If he can be persuaded to stand or sit on a box or table, so much the better. This brings him up nearer to camera-level and prevents him from wandering too far afield. Animals always photograph best from a viewpoint more or less on their own level; high viewpoints make them appear stunted and out of proportion.

Attempts to introduce humour into animal pictures by dressing the subject up in hats or clothing merely inspire the contempt of anyone who cares either for animals or photography.

Background. The background should be kept as plain as possible, preferably contrasting in tone with the dog's colouring. It is a mistake to pose a black or brown dog against a background in shadow, or a light-coated dog against a white or sunlit wall. Bare brick walls and trellis-work fences should be avoided along with all backgrounds with an assertive pattern or texture. The mottled shadow pattern of foliage and trees, and the spotty effect of light-coloured flowers are examples of backgrounds that have ruined more than one good photograph.

A plain neutral-coloured piece of cloth or blanket without folds or creases makes an admirable background—dark for light subjects, and grey or cream for dark. The background should be supported about three to four feet away from the animal, so that it can be thrown out of focus and kept free from the dog's own shadow. If the camera has a fixed focus lens, even greater care must be taken to see that the background is free from folds or creases.

The blue sky makes an excellent background; to make use of it, the dog must be made to stand on a low wall or the roof of a shed. Under these circumstances a colour filter must be used to correct over-sensitivity of the material to blue, so as to give tone to the sky area. It is better to choose a cloudless blue part of the sky than to include distracting cloud shapes. When using the sky as a background, it is wise to watch out for neighbouring chimney-pots and wireless masts. The filter, of course, calls for an increase in exposure.

Lighting. Side lighting—i.e., with the light falling across the subject at about 45° from above and slightly in front—is best, as it gives good modelling and shows up the texture of the dog's coat. Flat or frontal lighting destroys texture and modelling because all the shadows are cast behind the subject, where they cannot be seen.

Back lighting—i.e., when the sun shines from behind the subject—creates a halo of brightly-lighted fur or hair around the subject. At the same time, it leaves the background in shadow so that the subject stands out sharply from it. Since it also leaves the front of the dog in shadow, the exposure must be increased some three to four times to record detail in the deep shadows. Back-lighting calls for a deep lens hood or some equally effective shield to prevent the sun from shining directly on the lens.

Reflectors. Direct sunlight is a very contrasty form of lighting unless it is accompanied by plenty of indirect light from other sources—white clouds, light-coloured walls and similar reflectors. If there is no such reflection, it must be provided or the range of contrast between the highlights and shadows of the subject will be too great for the sensitive material to record.

A white cloth or a sheet of white paper can be

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

made to reflect the sunlight into the shadows so long as it is not brought close enough to distract the subject. The reflection from a mirror or bright metal sheet is too harsh and directional. Properly handled, the reflector can be made to bring out detail wherever necessary. It can also be used to throw a catch-light into the eyes, or accentuate characteristic features.

Taking the Picture. The spot should be chosen and all the necessary preparations made before putting the dog in position, because animals become bored, and show it if they are kept waiting in one place for long. The lens aperture and shooting distance should be worked out to give the necessary depth of field with a shutter speed of 1/50 second or faster.

The dog should be photographed from a viewpoint at about the same level and from an angle at which he appears in three-quarter view —i.e., neither square on nor in sideways view, but somewhere between the two. The head should be in such a position that nose, eyes, and ears can all be kept in sharp focus.

It is most important to catch the dog when it is wearing a characteristic expression. Large breeds, like Alsatians, Great Danes, etc., should be taken when they are looking dignified and alert, whilst terriers are more suitably shown in a playful mood.

It is easier to deal with a sitting animal than one which is standing, and there is less risk of movement. But photographs taken to depict show points need standing positions which clearly show the typical features to advantage. This sort of photograph calls for the co-operation of an expert in the breed.

A suitable word from the owner just before the shutter clicks will make the subject prick his ears, open his eyes and generally look alert and keen. But such encouragement must be used sparingly or the word will either lose its magic, or excite the dog and make him uncontrollable.

Another person's help can often be very useful in attracting the dog's attention. They can hold a favourite toy or a fresh bone and often obtain a useful reaction, or if some completely strange plaything is presented at the critical moment, the result is often highly amusing and worth photographing. But the dog must not see the object until just before the shutter clicks or the element of surprise will be lost. And such tricks seldom work twice at one sitting.

Close-ups. Head-and-shoulder portraits of dogs require even greater care. There is always a risk of distortion in a close-up picture. Good quality lenses of normal focal length will allow considerable enlargement of a portion of a negative, and in practice it is better to work at 6 feet and enlarge the negative than risk distortion by coming close to the subject.

The most satisfactory way out is to use a long-focus lens as it gives a large-sized image at a reasonable distance. With the decreased depth of field of such lenses, accurate focusing is essential. Head studies of long-nosed dogs, like Borzois and collies, are difficult because the depth of field must be considerable to cover the entire head from nose to ears.

Here again three-quarter and profile studies are preferable to full-face portraits.

Action Photographs. Action photographs of dogs out-of-doors call for shutter speeds of anything from 1/200 to 1/500 second.

A running dog is best photographed by swinging the camera in the same direction as the movement, and making the exposure with the camera actually moving. If the dog is jumping over an obstacle, the shutter should be released at the top of the jump when he is moving neither up nor down.

An alternative way of photographing dogs in action is to use a synchronized speed flash or flashgun. With these aids, movement of almost any speed can be frozen.

Indoors. With a lens aperture of *f* 6·3, a fast panchromatic film, and a sunny room, good indoor photographs can be taken of any normally well-behaved dog. It is better to choose a room with plain distempered or papered walls and a floor-covering that is without a pattern. As much of the furniture as possible should be moved away to leave a reasonably clear area for working in.

Reflectors and/or artificial lighting should be brought in to relieve shadows and the subject should be posed as near the windows as possible, but away from shadows cast by the window-frame.

The camera should be mounted on a tripod or support and worked at the fastest shutter speed that conditions permit. If Photoflood lamps are used, they should be kept well away from the animal or it may be distressed by the intense light. Flash, on the other hand, does not often worry animals, and electronic flash, in particular, seems to go completely unnoticed.

Puppies. Most puppies are intensely active, and unless the subject is very young, or full and sleepy, the task of photographing it should be treated as action photography.

An old slipper or hat, held out by the assistant, can generally be relied upon to start something worth photographing, and a sudden strange noise will often make the puppy stop short in an interesting attitude. A sleepy pup cradled in a box or basket is easy to photograph and generally worth taking. It is particularly necessary when photographing tiny puppies to keep the camera down to their level.

Groups. Two or more animals together are very much more difficult to photograph than one. As soon as one looks right, the other is sure to move. If the dogs are free to roam about, it is wise to use as small a lens aperture as practicable to get the maximum depth of field. But the table-top technique is probably best, with willing hands to hold the dogs. The helpers should let the dogs go an instant before the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

shutter clicks, while another assistant makes a sudden noise or shouts to attract the heads around into the same direction. Such groups should never be attempted single-handed, nor even with only one helper. P.J.

DOLLOND, JOHN, 1706–61. English optician. Constructed achromatic eye-glasses and combinations of lenses for the telescope (1757). Biography by Kelly (3rd edition 1908).

DOLLY. Camera support mounted on wheels so that the camera—particularly a cine camera—can be more easily moved about in the studio or on level ground. Similar supports are also available for studio lamps.

In filming, the term also means the action of moving the camera—i.e., tracking with the subject.

DONISTHORPE, WORDSWORTH. Dates unknown. English barrister. With W. C. Croft patented (1889) a cinematograph apparatus. Worked on the dispersion process of colour photography (1875).

DONNÉ, ALFRED, 1801–78. French professor of medicine. Worked on the theory of the daguerreotype process and took one of the first (unsuccessful) portraits (1839). Produced daguerreotype photomicrographs in 1839. Devised the earliest method of printing from etched daguerreotypes 1839. In 1844 devised (with Foucault) a projection microscope.

DOPING PRINTS. Prints, especially on matt-surfaced or velvet papers, never look as brilliant or have such deep shadows when they are dry as when they are wet. This is the result of light scatter on the surface of the print.

The contrast range—and hence, the brilliance—of the print can be greatly improved by treating the surface of the paper with "dope", or oil reinforcement. Dope can be bought ready prepared from photographic dealers, or it can be made up as follows:

Turpentine	2 ounces	50 c.cm.
Mastic varnish	1 ounce	25 c.cm.
Linseed oil	1 ounce	25 c.cm.

The medium is rubbed well into the surface of the print with a piece of soft fluffless rag or the ball of the finger. The surface is then polished with a soft cloth until no streaks or marks are visible and the print is put aside to dry in a dust-free room. The disadvantage of this method is that drying is slow, and may take a couple of days or more. As a quicker alternative, a good brand of white shoe cream may be applied evenly and sparingly to the print with a soft cloth. The print is then polished with another cloth.

Once a print has been doped or polished, it is impossible to carry out any retouching; all blemishes should be removed before treating the surface. R.M.F.

DÖPPLER EFFECT. When a source of radiant energy moves towards or away from an observer, the observed frequency of the radiations is modified in proportion to the relative velocity of the source—e.g., as a locomotive with the whistle blowing passes through a station, the pitch of the whistle drops suddenly. When the engine is approaching the station, it adds its own speed to that of the sound waves travelling towards the observer. Immediately it passes the station the speed of the waves is reduced by the speed of the engine.

In astronomy this effect gives scientists information about the speed and direction of movement of stars. The frequency of the light waves from the star is modified according to its speed and whether it is coming towards or going away from the earth.

The effect is of interest in the recording of star spectra.

DOSIMETRY. Quantitative measurement of ionizing radiations, for example X- and gamma rays for the purpose of a continuous watch on personnel radiation hazards. These measurements can be carried out by instruments such as ionization dosemeters or by photographic means. The photographic method has the advantage over other detectors that it provides a permanent record, that it covers a much wider range of quantities of radiation and that it is particularly suitable for a large scale personnel monitoring survey. It has however the disadvantage that it does not provide a direct reading of the result, but requires processing and interpretation. The apparatus required consists of a film holder, the radiation monitoring film and suitable processing equipment.

Photographic Response to X- or Gamma Rays. The response of the photographic emulsion (usually X-ray film) depends on the quantity (or dose) of radiation to which it was exposed and also on the quality, i.e. the wavelength composition of the radiation applied. A film dosimeter should be capable of giving information on both quantity and quality of the radiation applied.

Quantity or dose. The units of quantity of radiation are the *röntgen* and the *rad.* The röntgen refers to a certain amount of ionization produced by the absorption of the radiation in air; the rad corresponds to the energy of 100 ergs absorbed per gram of any material. Both units are in practical use and differ numerically by about 6–10 per cent.

According to current recommendation the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

maximum permissible dose to persons occupationally exposed to radiation can be expressed as a dose rate. It should not exceed 5 rads per year for whole body exposures. This corresponds to 0.1 rad per week or, within a 40-hour week, to 2.5 millirads per hour.

Before a monitor film can be used for interpretation, the particular batch of emulsion must be calibrated, i.e. the relationship between dose in röntgens (or rads) and photographic density for standard processing conditions must be known. This can be carried out by using a high precision dose- or doseratemeter.

The Film-badge System. This consists essentially of the film holder and the film packet. The film holder is a container into which the film packet is inserted. It is usually made of plastic with an open window and with areas covered by metal absorbers or filters. These may consist of duraluminium, tin, cadmium, copper, lead or other material. They serve (*a*) to smooth out to some extent the quality dependence of the film, and (*b*) to aid the interpreter in the assessment of the quality of radiation applied. The quality can be derived from the densities appearing on the film below the various filters after processing. The holder is usually provided with a means of attachment to clothing, so that it can be worn by the radiation worker.

The film packet is generally similar to a dental film packet, although the type of film selected may be different. As very low doses of radiation have to be recorded, the fastest type X-ray film is preferably used. Films having a fast emulsion coating on one side and a slow emulsion coating on the other side of the base have the advantage of covering an extremely wide range of doses of the order of 1: 10,000. Photographic dosemeters cover a wide range of modifications in regard to size, shape, type of filters and sensitized material. In some cases use is made of photographic papers instead of film.

Dosimetry of Electrons and Neutrons. The response of photographic film badges to electrons is greatly affected by the absorption of electrons by the wrapping material and corrections have to be made for this in any calibration. Neutrons, being uncharged particles, have no

MONITORING FILM HOLDER. The film holder, made in plastic and containing an open window plus filtering foils, is worn by personnel subject to radiation hazard. The container holds a wrapped sheet of radiation monitoring film. A, plastic. B, clear window. C, cadmium foil filter. D, tin foil filter. E, hinge.

X-RAY FILM FOR DOSIMETRY. The speed of a normal X-ray film depends on the quality of the radiation (curve A—relative speed for a constant radiation dosage plotted against voltage of radiation). The maximum at 440 KeV corresponds to soft X-rays; for gamma radiation (200 KeV upwards) the sensitivity is less. By filtering the film with a 1 mm. thin metal foil a more even response to different radiation energies is obtained (curve B).

direct action on the photographic emulsion, but can be detected by indirect means, such as nuclear reactions caused either inside or outside the emulsion. In the case of so-called thermal neutrons (i.e. slow neutrons) the most efficient photographic response is achieved by placing certain foils of cadmium, indium, rhodium and others in contact with the emulsion or its wrapping.

In these foils electrons, and in some gamma rays, are released by neutron capture and thus photographic blackening can be achieved after processing. In the case of fast (high-energy) neutrons, hydrogen nuclei (protons) are set in motion by collision of fast neutrons with the gelatin of the emulsion. Using nuclear track plates or films, proton tracks will be formed and from their number per unit area conclusions can be drawn as to the neutron dose applied.

R. H. H.

Book: *Photographic Film Dosimetry*, by K. Becker (London).

DOUBLE-COATED FILM. Negative film—usually for the popular market—coated with two emulsions, one (the upper) fast, and the other slow.

The effect is to increase the tone range and exposure latitude of the film.

Double-coating is also used for some process materials to provide special scope for contrast control.

Not to be confused with bipack films, at one time used in colour photography.

See also: *Negative materials.*

DOUBLE-8 mm. Usual form in which 8 mm. cine film is made, exposed and processed. The film is actually 16 mm. wide, but with twice the number of perforations of regular 16 mm. film. It runs through the camera twice, being exposed only along half of its width the first time, and along the second half during the second run through. After processing the film is slit down

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

DOUBLE EIGHT FILM. This runs twice through the camera and thus carries two sets of images. After development the strip is slit down the middle to give two single lengths 8 mm. wide. (The film is here about 20 per cent larger than natural size.)

the middle to produce the 8 mm. width with its one perforation row. Super–8 film is usually packed in single 8 mm. widths.

See also: *Cine camera; Cine film; Cinematography.*

DOUBLE EXPOSURE. Intentional double or multiple exposures are often used for particular effects, foı trick photographs, and for making composite pictures for advertising purposes.

When the images are to be simply superimposed—e.g., for making a ghost photograph—one exposure is made after the other without changing the film or plate. In this case the highlights of each image are visible where they lie over the shadows of the other. Where two highlights coincide there is no second image since both appear as white paper on the finished print, and where two shadows coincide the result is simply a single tone of black.

Where each image is to appear separately on the film without any overlapping or ghost effect, the method is to mask off parts of the plate in turn while other parts of the plate are being exposed. The simplest way of doing this is to cover half of the lens at a time. This can be done with a lens cap, one half of which is cut away. The cap is adjusted so that one half of the picture seen in the focusing screen is masked off. The first exposure is made and then the cap is rotated through 180° so that it masks off the part of the plate already exposed. The second exposure is then made. In this way the whole of the plate is covered in two separate exposures. This is the standard method for making pictures in which the same person appears twice. It is essential for the half-mask to fit close up to the lens or the join will show.

In the older types of camera double exposure may occur accidentally and generally this is the photographer's fault through forgetting to wind the next exposure on. Otherwise it can be a fault in the film transport mechanism, or—very rarely—shutter bounce (when the shutter momentarily bounces open again after closing from the first exposure).

Most modern cameras have some double-exposure prevention device. On some models, however, this device can be disengaged so that double-exposures may be made when desired.

See also: *Film transport; Faults; Tricks and effects.*

DOUBLE EXPOSURE LOCK. Mechanism fitted on many modern roll film and 35 mm. cameras to prevent accidental double exposure. This is done by coupling the shutter wind or release to the film transport mechanism.

See also: *Film transport.*

DOUBLE EXTENSION. Amount by which the front of a field, technical or similar camera can be extended—e.g., to twice the focal length of the normal lens. It is used for taking close-ups and is also necessary when long focus lenses are used on a camera.

See also: *Extension of camera.*

DOUBLET. Name still sometimes given to a compound lens of the rapid rectilinear type but more commonly applied to the cemented combination of a positive crown lens with a negative flint lens.

DRAM OR DRACHM. Unit of weight equal to 60 grains ($\frac{1}{8}$ ounce) in apothecaries' measure, and $27\frac{11}{32}$ grains ($\frac{1}{16}$ ounce) in avoirdupois measure. Also denotes 60 minims ($\frac{1}{8}$ ounce) in fluid measure.

See also: *Weights and measures.*

DRAPER, JOHN WILLIAM, 1811–82. American professor of chemistry. Great investigator in the field of scientific photography. He was a pioneer daguerreotypist associated with Samuel F. B. Morse and also an independent discoverer of the law of photochemical absorption, since known as the Draper-Grotthuss Law. Probably also the first observer of the retrogression of the latent image in daguerreotypes. In 1840 he published the first paper on portrait photography, and took the first successful ones. Produced the first daguerreotype photographs of the moon and of the spectrum (1840). Collected works: *Scientific Memoirs* (1878).

DRAWINGS FROM PRINTS. It is possible to make a hand drawing with waterproof ink over the top of a photographic image and then to bleach away the image, leaving only the drawing on the paper.

See also: *Bleach-out process; Sketch photographs.*

DRIFFIELD, VERO CHARLES, 1848–1915. English chemist and amateur photographer. Undertook in 1890, with Hurter, the famous scientific study of the characteristics of photographic emulsions (H. and D. curve), and created photographic photometry. Both received the Progress Medal of the Royal Photographic Society in 1898 "for their work on the determination of the speed of plates". A Memorial volume of their collected papers was published by the R.P.S. in 1920.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

DROP BASEBOARD. Term for the base board of a stand camera which is hinged to allow it to be swung down when a wide angle lens is in use so that it does not intrude on the wider field of such a lens. The drop baseboard is most commonly found on press cameras.

DROPPING BOTTLE. Glass bottle specially designed for pouring liquids drop by drop. The bottle has a ground-in glass stopper grooved half-way down on opposite sides. Corresponding grooves in the neck of the bottle enable the stopper to be turned to allow the liquid, when poured, to flow out in drops. Turning the stopper so that the grooves do not coincide closes the bottle.

Dropping bottles are useful for adding small quantities of solutions—e.g., wetting agent, developer improver, potassium bromide solution—to processing baths. They do not provide an accurate kind of measure.

DROPS. Drops are frequently used as a unit for measuring small quantities of liquid. But the size of a drop is by no means constant—it depends upon the nature of the liquid and the shape of the bottle lip or the dropper. For this reason the custom of regarding drops and minims as the same thing (or taking 20 drops as 1 c.cm.) is unreliable although it is near enough for most of the comparatively dilute aqueous solutions used in photographic processing.

DRYING

When negatives and prints have been processed they may be dried by various methods. The system used may largely be decided by the equipment available, although efficient drying is easily achieved without any special equipment, provided sensible care is taken.

Image density. The rate and other conditions of drying have some effect on the final density of the image. Hardening treatments during processing yield images of slightly lower final density, while rapid drying methods may produce higher densities. This is of practical importance only in scientific photography where the exact image density is quantitatively significant. In all cases however uneven drying tends to produce areas of different overall density, appearing especially pronounced when drops of water adhere to the emulsion surface and locally slow down drying.

PLATES AND FILMS

Once plate or film negative materials have been washed they should be dried as quickly as possible because all the time they stay wet they run the risk of being damaged.

To avoid drying marks, the negatives should be shaken and wiped free of water after washing. There are various types of chamois or viscose sponges available for wiping the surface of the emulsion, but unless they are kept absolutely clean and free of embedded dust, grit, etc., they may leave serious scratches down the whole length of a film or right across a plate.

It is advisable to put the film through a dish of water containing a few drops of wetting agent. When the film is hung up to dry, the water will drain off evenly.

It is perhaps safer to add a few drops of wetting agent to the last change of the washing water, and when the films are hung up to dry, the water will then drain off evenly without assistance.

Where the washing water is hard, a few drops of hydrochloric or acetic acid may also be added to the last lot of water. This will prevent scum deposits on drying.

Plates are best dried standing up in a wooden plate rack. There must be plenty of room for the air to get between neighbouring plates; if the plate rack grooves are set too close, only alternate grooves should be used.

Sheet films are best pinned up by one corner or hung from small film clips.

For roll and 35 mm. film, a normal film clip is fastened to one end, and the film hung up by it and weighted down by a second clip on the other end.

A number of modern drying units take the complete reel of a film tank and so make it unnecessary to touch the film until completely dry.

Drying Room. The room where the film is hung should be free from draughts or air currents that would stir up dust. For the same reason no one should be allowed to enter the room until the film is dry. While it is still wet, the gelatin surface has an uncanny affinity for stray dust particles, and once such particles become attached to the emulsion they are very difficult to remove. In summer it is wise to see that the drying room is also free from insects.

DRYING NEGATIVES. Left: *Plates are dried standing up on edge in a plate rack.* Centre: *Sheet films can be clipped on a line.* Right: *Roll and 35 mm. films should hang from a clip.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Forced Drying. Negatives dry faster in a stream of warm air. Special film driers are available which blow heated air over the film surface and commercial drying cabinets generally incorporate a small heater unit and a fan for the same purpose. The air is usually filtered to remove any dust.

It is never wise to attempt to dry a negative in front of an electric radiator because this sort of heat dries the surface of the gelatin more rapidly than the deeper layers, causing the film to curl violently. This effect is overcome in commercial drying equipment by using specially filtered infra-red radiation of wavelength longer than 50,000 A. Heat rays of this wavelength are absorbed by the moisture in the film, but not by the gelatin layer.

High Speed Drying. Really rapid drying calls for more extreme measures.

The popular method among press photographers is to immerse the film for 3–4 minutes in 80 per cent (not stronger) pure alcohol or colourless industrial methylated spirit. This largely displaces the water in the emulsion, and the negative will then dry in 3–4 minutes in a current of air.

Another way is to harden the negative in a solution of 1 part formalin in 30–40 parts water. It can then be washed in one or two changes of nearly boiling water and dried in a few minutes in front of a fire in a current of air.

For temporary drying the wet negative may be soaked in a saturated solution of potassium carbonate for 1 minute, and wiped clean with a piece of chamois leather or viscose sponge. It can then be printed immediately. Such a negative must be rewashed and dried normally later on. When rewashing, it should first be immersed for 3–4 minutes in the minimum amount of water needed to cover it. Putting the negative in a large volume of water straight away may cause reticulation of the emulsion.

PRINTS

After they are washed prints may be allowed to dry either naturally, or they can be dried quickly with the help of heat. Glossy prints may be glazed with the assistance of heat, usually from a special glazer-dryer.

Natural Drying. After washing, the prints are well drained or blotted with photographic blotting paper to remove all surplus water. Photographic blotting paper is a specially manufactured type of blotting paper which is free from surface fluff and contains no chemicals likely to stain the print.

After blotting, the prints are laid singly, face down, on a clean, smooth towel or tablecloth, and left until they are dry. Woolly materials are unsuitable, as they leave the print surface covered with fluff which has to be rubbed off afterwards. Coloured materials are also unsuitable, because they are liable to stain the print surface if the colours are not fast.

PRINT DRYING RACK. This consists of a series of frames with muslin stretched over them. The frames may be supported above each other in a covered rack to save space.

For large-scale drying, the prints may be laid on muslin stretched on wooden frames in a warm, dry atmosphere away from dust.

Alternatively, large pictures can be clipped together in pairs, back to back by one corner, and hung up to dry on a line. They may curl to some extent, but are easily flattened out afterwards (see below).

Heat Drying. Prints may be dried quickly by holding them in front of a fire or radiator. They must be kept moving, and turned over whenever they start to curl. They should not be allowed to become bone-dry, as the gelatin surface may then crack during flattening.

A glazing press can also be used to dry non-glossy prints quickly. Drying takes longer than for glazed prints, but it is still quicker than natural drying.

The glazing plate is taken out of the glazer, and the glazer is then heated up as for normal glazing. As soon as it is hot, it is switched off. The wet prints are laid on the glazing plate, face up, and all surplus water is blotted off. The plate is then replaced in the warm press, and the apron is fastened down over it. The prints thus dry fairly slowly in the press as it is cooling down. This method has the advantage that the drying speed is slowest at the time when rapid drying would be undesirable because it would cause the prints to curl violently.

The prints should be taken out of the press before they become bone-dry and brittle.

Flattening. Most prints, particularly large ones, tend to curl inwards during drying and must be flattened before mounting or filing. Very dry prints tend to curl more.

To flatten a print, it is laid, face down, on a soft but firm surface—e.g., a board or table covered with a layer of cloth. A ruler or straight edge is gently pressed diagonally across the back of the print and the print is drawn under it by the corner.

This will reverse the curl at one corner. The amount of curl taken out of the paper can be controlled by adjusting the weight on the ruler and the angle at which the print is drawn away from it. The greater the pressure on the ruler

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

STRAIGHTENING PRINTS. Prints often curl during drying and can be straightened by drawing them backwards over the edge of a table or underneath a ruler.

and the greater the angle between the paper and the board, the greater the anti-curling effect.

The same procedure is repeated for the other three corners. The whole print is then curled outwards, and will become flat if placed underneath a book for an hour or two.

The pressure of the ruler or straight edge must be applied with care, or the spot where it was pressed down may crease the print.

If the prints are too bone-dry, this way of flattening may crack the gelatin surface.

Most flattening methods, when applied to large prints, straighten the print out as a whole, but leave the edges wavy. This can be remedied in two ways:

(1) The print is laid face down on a clean sheet of paper. The back is slightly damped at the edges with a wet cloth or sponge until it just starts to go limp. A sheet of fairly absorbent paper—e.g., white blotting paper, or even a sheet of newspaper—is held in front of a fire or radiator until it is really dry and about to scorch. This sheet is then quickly laid over the back of the print, covered with a sheet of cardboard, and put under pressure for a few minutes. If necessary the process is repeated until the edges of the print are quite dry and flat.

(2) The back of the print is damped as before, and the print covered with a sheet of white blotting paper. It is then pressed by running a moderately hot household iron evenly over the whole print area. The print is finally covered with a sheet of cardboard and put under pressure until cold.

Glazed prints, if they curl at all, should be flattened by drawing them under a ruler (above), but taking care to avoid cracking the glazed surface; either of the wet methods would destroy the glaze. Usually, however, glazed prints flatten out of their own accord once they are cold. L.A.M.

Books: *Developing*, and *Enlarging*, by C. I. Jacobson (London).

DRYING EQUIPMENT. Sensitized materials can be dried after processing by simply leaving them in a dry, dust-free atmosphere for several hours. Films are simply suspended from a film clip and weighted at the bottom end; plates are stood on edge in a plate rack, and papers are spread out, emulsion side up, on muslin stretched across an open frame.

But there are drawbacks to natural drying: it is slow, the soft emulsion is left exposed to dust and damage for a longer time; and in bulk processing plants it calls for a disproportionate amount of space.

Negative Materials. Drying can be speeded up by keeping a stream of dry air constantly moving over the surface of the emulsion. This is done by suspending the film in a drying cabinet.

Cabinets are usually designed to take a number of lengths of film at a time, but small types taking a single length are also made.

The principle is the same in every case. The cabinet is usually made in the form of a sheet metal cupboard with rods at the top from which the films can be suspended. An electric fan draws air into the cabinet through a dust filter and over an electric heating element. After passing around the films, the air is exhausted at the top of the cabinet.

The temperature inside the cabinet is indicated by a thermometer dial on the front and is regulated by an external switch either controlling a thermostat connected to the heating element, or switching one or more sections of the element in or out as required.

Cabinets of this type can be equipped with hanging rods for up to 100 lengths of roll film, or with racks for plates and cut film in sheaths.

In establishments where large quantities of processing are handled, it is common to use infra-red lamps to enforce rapid drying. These effectively dry the emulsion throughout its

DRYING CABINET FOR FILMS. The films are suspended above a low-power heating element, with a fan below to keep up a constant movement of warm air. A muslin screen filters the incoming air so that it is free from dust.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

COMPACT 35 mm. FILM DRIER. This takes the film on its spiral reel direct from the developing tank. Similar driers are also available for other film widths from 16 mm. cine to 70 mm. film. The motor driven fan blows warm air through the film on the reel, while the air stream also rotates the reel. A, film on reel. B, fan blade connected to reel. C, motor driven drying fan. D, motor. E, heating coil. F, air stream.

depth in as little as two minutes; special precautions are, however, necessary to prevent the emulsion from melting.

Single-reel dryers take films on their spiral reels from developing tanks. Such dryers consist of a cylinderical housing into which the film reel is inserted from above, while a fan blows a current of air through from the bottom. The dryer may have a built-in heater for warm air drying. Single reel dryers of this type are available for the reels of normal roll film tanks, as well as for large capacity 35 mm. and 16 mm. cine film reels holding up to 100 feet of film. The main advantage of such a dryer is that the film need not be handled at all while wet, and is only unloaded from the reel when dry.

Prints. Special types of equipment are not generally needed for drying prints produced in quantities—i.e., in D. & P. work, in the picture postcard business, and for the press—as these are invariably finished in a hot glazer which automatically glazes and dries at the same time.

Special machines made for the purpose dry the prints between two bands of absorbent fabric which pass around a heated drum. The operation is continuous, the drum speed being controlled so that the prints stay long enough in the machine to emerge perfectly dry. Such machines usually have an output of the order of 200 8 × 10 prints per hour.

See also *Darkroom; Drying; Glazers and glazing machines; Processing machine.*

DRYING MARK. Marks left on the surface of the emulsion of a plate or film after the drying of isolated drops or streaks of water. The marks take the form of patches which are denser or less dense than the surrounding image and are left in the centre of a wet area that has taken longer to dry than the rest of the negative.

Marks of this kind show up on the final print and there is no cure for them once they are there. The only solution is to avoid them by either using a wetting agent in the final wash water, or wiping down the surface with a viscose sponge or chamois leather before drying the material. Either of these methods will prevent drops from forming on the surface.

It is also important to allow drying to proceed evenly; any attempt to speed matters after the negative has partly dried is always apt to leave uneven densities where the last patch dries off. This can be particularly important when matched negatives are required, as in colour printing with separation negatives. For this reason it is usual to allow separation negatives to dry naturally, all in the same position (relatively), so that any uneven densities due to drying will be in the same position on each negative.

Another type of mark which is often termed a drying mark is simply a limey deposit left after drying a negative that has been washed in hard water. Either of the above methods of preventing drops will work equally well here, or once the negative is perfectly dry, the marks can usually be rubbed away with a dry finger tip. Persistent lime deposits can be cleared by bathing the negative in a weak solution (1–2 per cent) of hydrochloric or acetic acid.

DRY MOUNTING. Popular way of sticking prints to a mount with shellac tissue (or similar material) with a hot iron or press.

See also: *Mountant; Mounting prints.*

DRY PLATE. In the earlier days of photography, when the wet collodion process was still popular, it was customary to refer to gelatin coated plates as dry plates. Nowadays all plates outside the photomechanical reproduction industry are gelatin coated and the term dry plate is no longer used.

DUBOSCQ, LOUIS JULES, 1817–86. French optical manufacturer. Used (1849, with Foucault) arc lamps for projection. Manufactured the Brewster stereoscope in 1851 and was probably the first Frenchman to make stereo photomicrographs (1857). Constructed apparatus for synthesizing motion from stereo series (1852), and for taking microphotographs. Built the Polyconograph camera for travellers (1861) which took 15 exposures on each plate.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

DU CAMP, MAXIME, 1822–94. French writer. Used photography (calotypes) during his travels in the Near East and published in 1852 *Egypte, Nubie, Palestine et Syrie* illustrated with 125 photographic prints.

DUCOS DU HAURON, LOUIS, 1837–1920. French scientist, pioneer of colour photography. In *Les Couleurs en Photographie* (1869) he formulated the principles of the additive and most of the subtractive methods of colour reproduction, although owing to wrong primitive colours and the lack of panchromatic materials not all of these methods could be executed at that time. In 1878, with his brother Alcide Ducos du Hauron, he published a pamphlet, *Photographie des Couleurs*, in which their methods of producing colour photographs were described. Proposed in 1891 the anaglyph method of stereoscopy. Received in 1900 the Progress Medal of the Royal Photographic Society "for the initiation of three-colour heliochromy as a working process". Biography by G. Potonniée (Paris 1939).

DUFAY, LOUIS D. Dates unknown. French photographer. Originator of an additive colour process first introduced as the Omnicolour plate, later as Dufaycolor film. The process makes use of an integral ruled-screen tricolour filter. The original negative image is reversed in development to make a colour positive transparency. A negative-positive Dufaycolor film was also current at one time for motion picture use.

DUHRKOOP, RUDOLF, 1848–1918. German portrait photographer, active in Hamburg from 1883 onward and later also in Berlin. Treated portraiture as an art, and worked mostly in the gum print and bromoil processes of the fin de siècle period.

DULL WEATHER. Sunless, overcast days are bad for most sorts of photography—because of the character of the light, not so much because there is not enough of it. The trouble is that the illumination comes from all directions; it is completely diffused and so it casts no definite shadows. Without well-defined shadows there is nothing to give relief and modelling to the subject, so that it looks flat and lifeless.

Where there is no choice, and the photographer must make the best of the existing light, the contrast of the final print can be improved by giving the minimum exposure to the negative, and by developing for longer than the normal time. The use of flash equipment offers a third solution that is very popular with press photographers.

Dull weather has its uses, however, and it is not always desirable to adopt special techniques to increase the contrast of the final print. Where the photographer deliberately sets out to portray a mood of depression, sorrow, or wistfulness, dull weather gives him the most suitable lighting conditions.

Close-up photographs of white or very light flowers, like lilies and convolvuli, are best taken in low-contrast lighting of this nature, and a dull day is often better than a sunny one for outdoor portraiture.

Interiors are generally photographed in dull weather to avoid the very strong contrasts between sunlit windows and walls, and furniture in shadow. P.J.

See also: *Daylight.*

DUNCAN, CHARLES, 1870–1960. English photographer. Travelled all over the world taking pictures for Thomas Cook; photographed old masters and antiques for *The Connoisseur*. Autobiography: *A Photographic Pilgrim's Progress.*

DUPLEX SYSTEM. Proprietary system for running 9·5 mm. cine film in wide-screen as well as in normal form. Although interesting in its possibilities, it did not make much headway and disappeared again from the market. A similar system has also been proposed—but never realized—for an 8 mm. film.

The Duplex 9·5 mm. film has two perforation rows instead of one, the perforations still being positioned between the frames and not along the edges of the film. Both the camera and the projector must be designed for this type of film.

For normal filming the film runs through both camera and projector vertically, and the effect is the same as with the ordinary 9·5 mm. film. For wide-screen pictures the camera is held horizontally so that the film runs from side to side. The camera then only exposes the film along one half of the width, the images being beside each other instead of below each other. Once the film has run through the camera it is turned over and exposed a second time along the other edge.

STANDARD AND DUPLEX 9·5 mm. FILM. Left: *Ordinary 9·5 mm. film has one perforation in the middle of the film between each frame.* Centre: *Duplex film has two perforations between each frame but is exposed in the same way as ordinary 9·5 mm. film.* Right: *For wide screen dual use the Duplex film runs through the camera twice horizontally and is slit down the middle after processing. Similar wide screen images have been proposed for 8 mm. film.*

CC-0. Agamnigas Digital Preservation Foundation, Chandigarh

After processing the film is slit along the middle and projected as the 4.75 mm.-wide strip running horizontally through the projector. The image has an aspect ratio of about 1·6 to 1, giving the wide-screen picture. On projectors designed for this system, the film transport mechanism and spools can swing over from vertical to horizontal running.

See also: *Cine film.*

DUPLICATE COLOUR SLIDES. Colour transparencies can be copied by the simple process of re-photographing the original colour transparency on a second piece of colour reversal film of either the same or a different make. Suitable means of re-photographing are either a camera adapted for same-size reproduction (by an extension bellows or extension tubes) or contact printing of the transparency (after removal from its mount) on to the fresh film.

A copy made in either of these ways is not truly a duplicate. Transparency materials are essentially of high contrast so re-photographing will generally give a copy of unusably high contrast with empty highlights and blocked shadows. In addition, since all colour materials use dyestuffs which are less than perfect, the colours in the copy will be somewhat degraded and shifted in hue. Colour errors which are acceptable or unnoticeable in the original transparency become apparent since they are now twice as bad and in addition direct comparison with the original transparency is possible.

Equipment and Technique. With proper methods, it is, however, possible to make acceptable copy transparencies using simple equipment. The contrast of the copy transparency can be lowered without too great a loss of colour saturation by the use of a suitable light source or a simple contrast reducing mask.

Electronic flash as a light source for copying of colour transparencies gives acceptable results. It can be used either for copying in a camera or for contact printing. Units specially designed for colour slide copying are commercially available.

If a 35 mm. camera fitted with extension tubes or a bellows attachment is used, this is mounted above a light-tight box containing an electronic flash tube (the flash head of a normal unit). The box carries an aperture of suitable size in one side. The aperture should be just larger than the colour transparency to be copied and covered by a piece of flashed opal glass on the inner side. In addition to the flash tube the box should also contain a tungsten lamp so that the transparency can be illuminated for focusing.

Correct exposure can only be found by trial and error. Set the lens to a medium aperture for optimum definition and (since the exposure time is controlled by the flash duration) set the shutter to 1/50 seconds (if a focal plane type) or any speed with a diaphragm type. Exposure can be varied by giving a number of flashes as well as by varying the lens aperture.

Contrast and Colour Control. Contrast of the copy transparency can be more precisely controlled by first exposing a thin, soft, black-and-white negative by contact with the original. After processing this is bound up with the original transparency in accurate register to form a contrast-reducing mask. Registration becomes easier if the negative is exposed through the back of the transparency and is thus slightly unsharp. Such an unsharp mask also gives copies of apparently enhanced sharpness. The contact mask will lower the contrast of the original to a degree which will depend on the contrast of the negative, whilst leaving the colour saturation unaltered.

In every case filters can provide overall colour correction.

The filters used should be the dilute complementaries of the colour cast to be corrected. A transparency which is too yellow in balance can be corrected by filtering the light source with a pale blue filter; a transparency which is too blue is improved with a pale yellow filter. The correction filter can be placed at any point between the light source and the transparency (or between the transparency and the lens when using a camera).

An alternative method of copying transparencies which is used by commercial colour laboratories involves the use of inter-negative film. In this method a colour and contrast corrected negative is first produced on a special colour negative film. Prints on positive copy film can then be made from this negative.

G.W.A.

See also: *Colour printing technique; Reversal materials.*

DUPLICATE NEGATIVES. Valuable negatives that might be difficult or impossible to replace are often duplicated for safety. There are several ways of making a duplicate, but the most reliable is by double contact printing on to ordinary lantern plates.

The negative to be duplicated is first printed in the normal way on to a lantern plate with the emulsion sides in contact. The lantern plate is processed to give a positive, and then when dry printed again on to a second plate, emulsion to emulsion. When developed, the second plate is the required duplicate negative. By suitably modifying the exposure, development, and grade of the plates, the character of the final negative may be controlled within wide limits. Ordinary (non-colour sensitive) process sheet film can be used in the same way.

Duplicate negatives can also be made by photographing an ordinary contact print or enlargement from the original negative, but the gradation and definition are never as good as in a duplicate made by double contact printing.

It is also possible to produce duplicates without an intermediate positive—i.e., by reversing the positive image produced under

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the negative in the first place. This is done either by bleaching out the positive image and then exposing and developing out the remaining silver bromide, or by substituting a dye image for the unexposed silver bromide and then removing all the silver.

Straightforward reversal processing of the film exposed through the negative also yields a duplicate negative. Reversal film specially designed for this purpose may be used, but many of the slow fine-grain negative films are equally suitable. Most manufacturers issue specific instructions for reversal processing of their negative materials. Such materials are not recommended for producing reversal positives (e.g. from positive transparencies), since the base tint of the negative film would also tint the positives.

Special film is available for making duplicate negatives without an intermediate positive. The film has a speed about equal to that of contact paper and when it is exposed under the negative it develops direct into another negative. Such materials may either be prefogged emulsions where the reversed image is produced by the destruction of the latent image fogging by exposure to yellow or orange light (Herschel effect); or they may be films with a diazotype (dyeline) layer which directly yields a negative image from a negative. Such dyeline films are widely used in producing duplicates from microfilm negatives.

Duplicate negatives have a special importance in cinematography where the original negative is never used for making 35 mm. release prints; the original is used for much 16 mm. work, but is sometimes duplicated in preparing special effects such as dissolves and fades. Amateur films are mostly made on reversal film, and if a copy should be required it is made by printing the original positive direct on to reversal stock.

DUST. Dust is a nuisance at every stage in photography.

On the Lens. In time most camera lenses build up a coating of dust—in particular, box and folding hand cameras that have no protection in the form of a lens cap or hinged front. A dusty lens cannot form a sharp image and it tends to give veiled and foggy negatives. It can be cleaned by first removing the dust with a clean soft brush kept for the purpose, and then wiping the surface gently with a piece of clean chamois leather or lens cleaning tissue. Even better is a special anti-static cloth or brush; these do not induce static electricity, which causes dust to cling to the lens.

In the Camera. The opening and closing of bellows type cameras, in particular, sucks in dust that is always likely to settle on the back of the lens or on the surface of the emulsion. It is best removed by opening the back of the camera, loosening the dust with a soft brush, and blowing it out with blasts of air from a bicycle or car tyre pump—not by breathing moist air into it. Better still the dust may be sucked out with an ordinary vacuum cleaner. Care must of course, be taken not to distort and thus damage the bellows when doing this. Dust on the inner surface of the bellows can considerably lower the quality and the contrast of negatives. Bellows in such a condition should be re-blackened.

It is always easier to prevent dust from getting into the camera in the first place than to remove it once it is there. The camera should always be kept in its case when not in use; never opened longer or oftener than necessary and never carried loose in the pocket of a jacket or overcoat. It should also be given a thorough clean from time to time.

On the Sensitive Material. Specks of dust on the surface of a film or plate before exposure shield the emulsion and leave clear spots or pinholes on the negative. They can best be prevented by keeping dust out of the camera body (above) and film holders (below). Films or plates as they come from the factory can be assumed to be dust-free; they should not be allowed to lie face up in the darkroom when they are being loaded and the surface should never be touched with the fingers or brushed. If there is any reason to think that dust has settled on the surface of a film or plate, it should be shaken off by tapping the edge of the material lightly on the bench.

In Plate and Film Holders. If holders are carried around in a dirty case or cloth, dust creeps in at the edges and eventually finds its way on to the emulsion. While everything should be done to keep the holders away from dust, it is a good plan to draw the dark slides and blow out all the crevices at regular intervals. Particular attention should be paid to the velvet light trap. Dust harboured in it readily transfers itself to the dark slide and on to the emulsion.

Films are less likely than plates to acquire dust particles before exposure.

In the Darkroom. Two kinds of dust give trouble in the darkroom—ordinary dust and fine particles of photographic chemicals.

Ordinary dust should be reduced by the frequent use of a vacuum cleaner, not only on the floor, but on the bench and along the tops of cupboards. The darkroom floor should preferably be of non-dusting material without a carpet. The tops of processing solution bottles should always be wiped around before pouring out the solution to prevent any particles that have settled on the mouth of the bottle from being washed off into the solution. For the same reason all graduates and other vessels should either be kept upside down or covered when not in use; they should be allowed to dry naturally after washing and not be rubbed with a cloth, and they should always be rinsed under the tap before use.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Chemical dust is also created by allowing dishes that have contained solution to dry without first thoroughly washing them, or by neglecting to wash all places on the bench or floor where solutions have been spilled.

Chemical dust causes dark or clear spots or stains, according to its nature, on the emulsion surface of sensitized materials. It is generally the result of careless handling of darkroom chemicals, particularly fine substances like amidol. Here again prevention is easier than cure (since cure calls for tedious retouching). It is a sound rule to measure and mix all chemicals away from the darkroom.

It is wise not to dust or clean the enlarger or any other part of the darkroom immediately before use, as such action will leave dust particles floating about. The dust is potentially far more damaging in this state than when it is resting on top of the enlarger, shelves, etc. The darkroom should be cleaned at a time when no work is planned for some time afterwards.

In the Enlarger. Dust should not be allowed to accumulate on the enlarger lens or it will cause light scatter and consequent loss of sparkle and quality in every print made. This applies particularly to the back of the lens in vertical enlargers when the operation of the negative carrier and focusing movements causes dust to fall on to the lens.

Dust on the carrier glasses will show as white spots in prints and a similar effect will be produced if dust should be present on any glass surface near the carrier, such as a condenser or heat absorbing glass. Frequent cleaning of the entire optical system of enlargers is essential and carrier glasses should be cleaned and inspected for every negative enlarged. The simplest and most effective method of removing dust is, as mentioned above, to wipe the surfaces with anti-static cloth or one of the special brushes now available. Ordinary cloth is useless because of the static electricity induced by the rubbing. As a check that carrier glasses are clean, they should be focused on to a white paper on the easel, when any dust present can instantly be seen.

General Hints on Removing Dust. Most non-metallic surfaces—glass, plastic, celluloid, and the emulsion surface—tend to become electrically charged when they are rubbed with a cloth or brush. In a charged state they attract dust particles and hold on to them stubbornly. This is why dust can never be satisfactorily removed from such surfaces by rubbing; the more they are rubbed, the harder the dust clings. A single wipe over with a damp washleather is one very effective treatment. Any stubborn specks should then be removed separately with a corner of the washleather over the point of a pencil. Better still are the anti-static materials already mentioned above.

Dust is best cleaned out of crevices by blowing it out with a puff of air from a bellows. Miniature bellows can be bought which have the advantage of a very thin nozzle. Failing a small bellows, a cycle or motor tyre pump will do. Blowing moist breath into the part is worse than useless because it tends to mist over glass surfaces and start rusting in metal parts out of sight—e.g., in the shutter mechanism.

F.P.

DUSTING-ON PROCESS. Printing process using a support coated with a layer of gum arabic and a hygroscopic substance like honey, glucose or sugar—sensitized with a bichromate.

A coating of this nature becomes sticky with moisture that it absorbs from the atmosphere. But if light reaches any part of it, that part loses its stickiness. This is the effect that makes the process possible.

The sensitized surface is exposed to the light under a positive transparency. It is then left in the air but away from the light long enough to acquire the right degree of stickiness. The surface is then brushed over lightly with a powdered pigment of a suitable colour. Where the positive image has masked the surface, it remains sticky and holds the pigment. The operator is thus able to build up a positive picture which he can "fix" with the fixatif solution used by artists for crayon and pencil work.

This process can be used for printing a photographic image on materials like glass or ceramics by replacing the pigment with a powder that can subsequently be burned in or vitrified.

See also: *Printing processes (obsolete); Printing on special supports.*

DYE. Complex chemical used for colouring by molecular adsorption (as opposed to a pigment which colours by coating the substance with solid colouring matter). The actual colour of a dye is governed by the constitution of the dye molecule; the dyeing effect depends on the chemical nature of the substance being dyed.

Dye solutions can often be true solutions whereas liquid pigments are suspensions of solid colouring matter in a liquid vehicle.

Dyes are used in photography for colour sensitizing emulsions, for desensitizing emulsion, for toning transparencies and prints, to provide the coloured images in colour transparencies and prints and for retouching negatives and prints.

(1) As early as 1873, H. W. Vogel discovered that the use of a yellow anti-halation dye on collodion plates made them sensitive to green light. Subsequent experiments showed that a dye sensitizes a photographic emulsion to rays which are roughly of the same wavelength as those absorbed by the dye. The principle was progressively applied to gelatin emulsions as new dyes were developed and it is now standard

practice to sensitize plates and films to all colours of the spectrum—and it is even possible to make them sensitive to invisible radiations—e.g., infra-red.

Emulsions may be dye sensitized either by adding the dye to the liquid emulsion during manufacture, or by bathing the material in a dilute solution.

(2) Some dyes in solution—e.g., pinacryptol green—have the ability to make emulsions comparatively insensitive to actinic light. A plate or film immersed for a minute or so in such a desensitizing bath can subsequently be developed in yellow or weak white light.

(3) The silver image of a transparency or a print can be toned by first converting it into a colourless substance—e.g., silver iodide or cuprous iodide—(known as mordanting) and then immersing in a dye which is selectively absorbed on the substance and not by the gelatin. The result is that the image alone carries the colour. The dye toning process is also used in certain methods of making three-colour prints from separation negatives.

(4) The image of most colour transparencies, and prints made from colour negatives, consists of dyes. These are usually formed *in situ* during development by the interaction of oxidation products of the developer with colour couplers. As a result a dye image is formed in each emulsion layer together with the silver image, and after removal of the latter only the dye images remain.

(5) Water-soluble dyes of the same colour as the silver image—i.e., black, and the various cold and warm tones—can be used as an alternative to pigments for spotting out and retouching negatives and prints. The dye is absorbed into the gelatin and becomes part of the image instead of remaining on the surface. In the same way, dyes of various colours can be used to tint prints and transparencies by hand. L.A.M.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

DYE DESTRUCTION PROCESS. Process for making colour prints with a tripack material which, however, already contains the final dyes (and not just dye couplers) in the emulsions before exposure. After exposure, a suitable bleaching agent, acting in conjunction with the silver image produced during the first development, bleaches the dye in the image areas in proportion to the silver densities present. If the silver image is a negative, this results in the formation of a positive dye image, and in this form the process can produce positives from colour transparencies without reversal. For negative-positive printing the image is in effect reversal-processed before reaching the dye bleaching stage.

See also: *Colour history; Colour materials; Colour printing processes.*

DYELINE. Printing process relying on the action of light on diazo compounds. Widely used in office copying procedures and for making duplicates of plans, maps, etc. The process yields a positive image from a positive and the prints are developed by treatment with ammonia vapour or certain organic solutions. The main advantage of the dyeline process is the cheapness of the material which is essentially a suitably impregnated paper.

See also: *Diazotype.*

DYE SENSITIZING. H. Vogel, in 1873 discovered that certain dyes were able to extend the colour sensitivity of a silver bromide emulsion. Dye sensitizers since developed have made it possible for manufacturers to sensitize emulsions to all visible rays and a wide range of invisible radiations, depending on the requirements of the emulsion.

DYE TRANSFER COLOUR PRINTS

The dye transfer method of making colour prints on paper is a subtractive imbibition process in which the dyes from three separately prepared images are transferred in register to one sheet of paper to form the colour print. A considerable amount of control is possible and it may be expected to give better results than integral image colour printing papers, especially with difficult subjects or when working from a transparency in which the colour rendering is faulty.

A good set of separation negatives (including the usual grey scales) is the first requirement for the normal process. They may be made from a transparency or taken direct from the subject. The procedure is as follows:

(1) Three relief matrices are made from the separation negatives either by contact printing or enlargement using specially prepared matrix film.

(2) The matrix film is exposed through the base and then developed in a tanning developer.

(3) The surplus emulsion which has not been tanned by the developer is now washed away in hot water leaving an image which looks very much like an ordinary positive made on sheet film except that it is in relief with the thickness of the gelatin varying from a trace in the light parts to a relatively heavy amount in the shadows.

(4) The three matrices are dyed up in cyan (blue green), magenta and yellow dyes respectively.

(5) They are then brought in turn into contact with a sheet of special transfer paper which absorbs the dye out of the matrices. The finished

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

STAGES IN DYE-TRANSFER PRINTING. 1. Make positives on matrix film by enlarging three-colour separation negatives in turn. 2. Develop the three matrices in a tanning developer. 3. Fix the matrices. 4. Remove untanned gelatin by treatment with hot water. 5. After chilling, hang up to dry. 6. Carefully register the three matrices, tape together along two edges, and trim the other two edges. 7. Expand the matrices and dye each in its appropriate dye bath. 8. Treat the dyed matrix in the acid rinse. 9. Position first matrix on transfer blanket and transfer dye image to final support. 10. Locate subsequent matrices and transfer in register with first image.

print is therefore made up of three combined dye images.

The process divides itself conveniently into two operations: making the matrices and making the print.

Making the Matrices. Before starting to make the matrices three things have to be decided: the relative exposure for the three matrices which will give the correct colour rendering in the print; the actual exposures which will give a just perceptible density in the lightest parts of the matrices; the contrast to which they should be developed. The first of these is a problem common to all separate image colour-printing processes; it is dealt with by adjusting the printing exposures to give identical reproduction of the grey scales on each of the separation negatives. The second calls for the same technique as is used for finding the exposure for bromide prints—e.g., by test strips, exposure photometer, etc. The contrast to which the matrices are developed can be controlled by the composition of the developer and is largely a matter of experience, although the maximum density range of the separation negatives gives a fair guide. The vital factor in development is to make certain that each of the matrices receives exactly the same treatment. The easiest way to do this is to expose the matrices one after the other and to develop them either in separate trays on a rocker, or by the interleaving method in one dish. The danger is that all three matrices may be incorrectly exposed, whereas, if each matrix is treated separately, the fault can be found without wasting three sheets of film.

For amateur use there is much to be said in favour of separate development at room temperature (between 60 and 75° F.) with standardized agitation. As the speed of the matrix film varies with the development temperature it is wisest to find the exposure by the test strip method.

After development the matrices are put into an acetic acid stop bath and then washed off in hot water for about five minutes. The temperature of the hot water wash can be varied between 130 and 180° F. but must be nearly the same for the three matrices otherwise the expansion will not be the same and will cause trouble with registration.

Making the Print. The making of the actua colour print can be left until any convenient time. It is carried out by dyeing each matrix with the correct colour and then printing all three images by contact in register on to a single support.

One of the annoyances in the process is that the dye baths tend to go out of balance and have to be tested at intervals. The test is made by superimposing three dye images made from the same, or identical matrices. The resulting image should be grey. As the dyes are apt to give different degrees of contrast the test is best made with a step wedge matrix. If the dyes

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

are found to be out of balance they have to be adjusted by adding acetic acid to whichever ones are low in contrast.

After dyeing up and before making the actual transfer the matrix is rinsed briefly in acetic acid to remove the surplus dye. It is here that the four normal controls can be applied. These are: the addition of sodium acetate to the rinse to reduce contrast in the middle and shadow tones; the addition of calgon to clear the highlights; reduction of contrast by reducing the strength of the acid rinse; increase in contrast, especially of the highlights, by adding extra acid to the rinse and carrying over more dye from the dye bath.

In each of these controls there are three variables: the composition of the rinse, e.g., the amount of chemical added; the rinsing time; the quantity of rinse used. It is only by carefully standardizing the procedure that consistent results can be obtained.

Another possible means of controlling contrast is to add acetic acid or ammonia to increase or reduce contrast of the dyes. Unfortunately the dyes are not equally sensitive to these additions and it is difficult to keep them in balance.

The three-dye images must, of course, be transferred in register. This may be done either by registering the matrices beforehand or at the time of transfer. With the first method the matrices are taped down in register over an illuminator where either two edges are trimmed or holes are punched to provide a mechanical guide for subsequent transfers. This method is ideal when several prints are to be made, but the extra time and apparatus needed is unnecessary when making only a few duplicate prints.

Individual registration is simple; the only apparatus needed is a strong clip and a thin sheet of celluloid. After transfer of the first colour image the print is covered with a sheet of celluloid and the next matrix registered on top of it. When the register is satisfactory the matrix and transfer paper are clipped together, the celluloid removed, and the matrix rolled or squeezed into contact. With practice the whole process should not take more than one or two minutes. The only disadvantage of the method is the possibility of scratching the matrix while registering it or while removing the celluloid.

Duplicate Prints. The process has the great advantage that after one good print has been made, duplicates can be produced quickly and cheaply. The average cost of one print only is rather more than for a similar carbro print because of the cost of the matrix film; but the actual cost of making duplicates is much less. One set of matrices can be used for up to 150 prints and the time taken for making each print varies from 10 to 40 minutes depending on the working conditions.

Dye Transfer v. Carbro. The chief disadvantage compared with carbro is the inability to make adjustments for bad register between the three-colour images. With careful work this should not cause any difficulty if the separation negatives are made from a transparency. If they are made direct from the subject the camera must be capable of exposing the three negatives in exactly the same plane and the lens must be well corrected for chromatic aberration.

At first sight the number of bottles and the space needed for working the process seem rather formidable, but the amateur who is not primarily concerned with making a print in the shortest time will only need space for five dishes of the size of print to be made, and access to a sink and hot water.

The control which can be applied during the process is considerable and this often tempts the novice to inaccurate work. In fact, a great degree of contrast control is possible, but this latitude often makes it more difficult to produce a good print unless the process is carefully controlled. The latitude in exposure of the matrices is on the other hand small and does not amount to much more than 5 per cent under or 15 per cent over the ideal exposure.

The latest development in the process is the panchromatic matrix film which makes it possible to produce colour prints direct from negative colour transparencies without the need for colour separation negatives. At first sight the process seems to have every advantage, but it is difficult to judge the quality of the transparency or to make a good colour print unless the transparencies are taken under standardized conditions or with a grey scale included in each picture. This fact may more than outweigh the saving in time for making separation negatives. H.

EASTLAKE, SIR CHARLES LOCK, 1793–1865. English painter. Chief adviser to the Prince Consort and the Government on art. Director of the National Gallery and President of the Royal Academy, 1852; first President of the Royal Photographic Society, 1853–5.

EASTMAN, GEORGE, 1854–1932. American photographic manufacturer of Rochester, New York. His first products were plates for which he introduced machine coating in 1879. Introduced paper roll films in 1884 as negative material, in 1888 transparent film, and also in 1888 the "Kodak", the first of the now famous series of roll film cameras. In 1891 the daylight-loading film was introduced. The slogan, "You press the button, we do the rest," brought the taking of photographs to the millions, and popular photography spread over the civilized world. As a direct consequence, the Eastman Kodak Company provided a dramatic, almost fantastic example of growth and development in industry, and it has founded and supported a unique chain of research laboratories. Eastman's commercial manufacture of roll film provided the basic material for cinematography and made the huge film industry possible. Eastman introduced 16 mm. reversal film for amateur cinematography (and the necessary camera and projector) in 1923 and developed various colour photography processes to commercial application. Received the Progress Medal of the Royal Photographic Society in 1927.

Was one of America's greatest philanthopist. Eastman died by his own hand ("My work is done—why wait?"). Biography by C. W. Ackerman (Boston and New York 1930).

EBERHARD, GUSTAV, 1867–19??. German astrophysicist. Published numerous investigations on spectroscopy and on photographic photometry. Described the Eberhard effect (1926, 1931).

EBERHARD EFFECT. Dependence of the density of small areas of the developed image upon the size of the area. This is due to the diffusion of developer across the border between areas of differing exposure level, and to the increased density difference which occurs on a micro scale across the border compared

THE EBERHARD EFFECT. Microdensitometer traces show that the average density of small areas is higher than that of large areas. In all cases the density tends to rise near the edge of an area adjacent to a much thinner area. (d is the distance across the image.)

with that occurring on a macro scale between the centres of such areas. The smaller the areas in question, the greater will be the contribution towards their average densities of the border fringes which are subject to this enhanced density difference. The effect is observable for image sizes of less than approximately 1 mm.

See also: *Edge effect.*

EBONITE. Form of hard-vulcanized rubber, usually black, at one time much used in photography. It is relatively easy to mould or machine into camera parts and darkroom equipment, and it is not affected by photo-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

graphic chemicals. Ebonite is, however, being more and more displaced by harder and tougher plastics. Nowadays its principal use in photography is for X-ray film processing tanks of up to 5 gallons capacity.

EBURNEUM PROCESS. Obsolete process brought out in 1865 by E. Burgess, a Norwich photographer. A positive image made by the carbon or collodion process was stripped and transferred to a support of imitation ivory. It was superseded by the Ivorytype which was much easier to produce.

ECOLOGICAL PHOTOGRAPHY. Ecology is the study of relationships under which living things exist together in their natural surroundings. Photographic records concerned with these studies include an appreciable quantity of straight-forward natural history pictures. But the quantitative assessment of ecological conditions usually involves a specialized application of aerial photography to investigate the distribution of plant life on a large scale.

The Nature Conservancy acquires Nature Reserves and is therefore concerned with ecology and conservation. These Reserves are managed under long-term management plans. Before management plans can be prepared, it is desirable to map the areas and also to carry out soil, vegetation, geological and physiographical surveys. Aerial photographic interpretation is playing an increasingly important role in carrying out these surveys.

The apparatus and exposing techniques used in ecological surveying are substantially the same as in normal aerial surveys. The amount of information obtainable depends largely on the skill of the interpreter.

Effective interpretation requires considerable experience with an extensive knowledge of the earth and life sciences, as well as a knowledge of photography. Interpreters with these dual qualifications are few and therefore it is necessary to find means of simplifying the interpreter's task by increasing the tonal contrasts on the photograph. Colour photography, filter and film combinations used wisely can greatly facilitate their work.

Films and Filter. The choice of film and filter combinations is of paramount importance in interpreting aerial photographs. This especially applies to the interpretation of vegetation where the tonal contrasts are usually low. The grey tones of the photograph are due almost entirely to the amount of light reflected by the object to the camera. Colour does affect the tone slightly but so little that it can be considered negligible. Light reflection depends on a number of contributory factors, the two most important being the position of the sun in relation to the camera and the texture of the surface being photographed. The tonal contrast between vegetation species under natural conditions is very limited. This especially applies to panchromatic film, which although sensitive to a wide range of colours, is not very sensitive to green light from foliage. A green filter is often used to remove both the red and blue light, thereby intensifying the contrasts in the green. Yellow filters are almost invariably used in aerial cameras. These filters cut out the blue light and this improves the haze penetration for maximum contrast on the photograph.

Infra-red film has two characteristics which assist the photographic interpreter. They are the unusual tonal rendering and its haze penetration, although the latter is not as efficient as is often supposed. Objects of high infra-red reflectance (chlorophyll content) appear very light in tone and those of low reflectance dark in tone. Extreme contrast is therefore obtained between some vegetation species. Infra-red is particularly helpful in the identification of trees, although deep shadows hide some detail. It is also of great value to physiographers and map makers because it enables the edges of water to be delineated with great accuracy, as clear water shows black on the photograph.

Colour photography has had limited use in Britain, partly because of greater cost and partly because of unfavourable weather conditions; reasonable colour rendering is possible only during a relatively limited period of the day, but high-speed colour emulsions can be valuable for specific purposes—e.g. to isolate areas of a particular species of grass from its associated vegetation. B.H.G.

EDER, JOSEF MARIA, 1855–1944. Austrian scientist. Made outstanding contributions to photography, photochemistry and photomechanical work. In 1878 Eder won the great gold medal and one hundred ducats, the prize of the Wiener Photographische Gesellschaft (Photographic Society of Vienna), for his work on the action of chromic acid and chromates on gelatin and other organic substances. In 1879 his thesis on *The Chemical Action of Coloured Light* was published. In 1880 Eder became Professor of Chemistry at the Royal Technical School in Vienna. Soon after this he produced his comprehensive *Handbook of Photography*, which ran into many volumes and many editions. In 1889 he was appointed director of the Graphische Lehr- und Versuchsanstalt (Graphic Arts Institute), the greatest school of graphic art in the world. Finally, amongst other books, there is his great *History of Photography*, the last edition (German) of which appeared in 1932, and was translated by Edward Epstean in 1945. He received in 1884 the Progress Medal of the Royal Photographic Society for his work on silver chloride emulsions for gaslight development papers (1881). Biography by F. D. Worschak and O. Krumpel (Vienna 1955).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

EDGE EFFECT. Generic term covering the various effects which can occur at the boundary between portions of the developed image of differing densities.

During development, the developer in the vicinity of a heavily exposed area becomes rapidly exhausted and the rate of development decreases. In the areas corresponding to less exposure adjacent to the heavily exposed area, however, the developer remains comparatively active. Due to lateral diffusion of this more active developer across the boundary between the two areas, a local increase in the rate of development takes place just inside the edge of the heavily exposed area, and this narrow strip develops to a higher density.

Similarly, in an area that has received only a low exposure, the developer remains relatively fresh and active. In adjacent areas corresponding to higher exposure levels, however, the developer becomes more and more exhausted as development proceeds. This relatively exhausted developer diffuses across the boundary into the lightly exposed area and lowers the activity of the solution at this point. Thus just inside the edge of the area of low density is produced a line of even lower density.

The net result of these two effects is the production, at the actual border between two areas of the type described, of a density difference greater than that which exists between the gross areas concerned. This enhanced edge contrast results in greater image sharpness, and is an effect which is in some instances sought after. The effect is emphasized by the use of a developing solution which exhausts rapidly during development, and by the avoidance of agitation.

EDINOL. Para-aminosaligenin. Developing agent. Now obsolete for that purpose.

Formula and molecular weight: $NH_2C_6H_3OHCH_2OH$; 139.

Characteristics: White powder, similar to para-aminophenol in its developing action.

Solubility: Fairly soluble in water.

EDISON, THOMAS ALVA, 1847–1931. American inventor. Up to early in 1928, had taken out 1,033 patents among which were telephones, automatic telegraph systems, the phonograph, the first dictograph, incandescent electric lamps, and in 1891, the Kinetograph and Kinetoscope for taking and viewing serial pictures. Was probably the first to use on a practical scale film perforated at the sides, and was also the first to combine the projection of pictures with his phonograph to produce the first practicable, though far from perfect, sound film. Biography by F. L. Dyer and T. C. Martin (New York and London 1910).

EDITING

Arrangement of the individual shots of a cine film in the final order in which they are to be presented for the best filmic effect. This is the final stage in the production of a film. In a simple amateur film it involves sorting out the takes into their correct order, rejecting unsatisfactory ones, varying the length of shots to the mood of the film and joining all the resulting pieces together in the chosen order. In a more ambitious film judicious editing can control the tempo and even the story content of the film itself. In feature films editing is thus at least as important as scripting and direction.

Editing has a physical and a creative side. The first involves the sorting out of the shots and the splicing together. The second is concerned with cutting the shots to the right length, selecting the order in which they shall be joined and creating appropriate juxtaposition of scenes to convey ideas or impressions which may not be inherent in the individual scenes.

In the scripted film it is the editor's job to interpret the intentions of the script-writer and the director to produce the desired final effect.

Equipment. The main item of equipment is an animated viewer, preferably one that runs at a constant speed so that accurate timing of the shots is possible. Amateur viewers do not have this refinement. Many amateurs use their projectors instead, although inconvenient.

A good splicer is a necessity for joining the strips of film together with speed and accuracy. Film cement is the solvent used for what is actually welding and not a cementing operation.

Rewinders, spare spools and a winding-off plate are needed to enable film to be wound on and off the spools and generally handled with ease during the editing.

The sorting equipment often takes the form of a pin rack on which a row of film strips can be hung and sorted into order as required. Amateurs seem to favour an array of small tins numbered and stuck on to sheets of plywood of a convenient size. Storage tins serve to keep all the pieces of film identified and available.

ANIMATED VIEWER. The different units are laid out on an editing bench for easy manipulation. A, normal feed spool. B, viewing screen. C, lamphouse. D, normal take-up spool with geared winding handle. E, film cement. F, splicer.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The smaller items of use include white cotton gloves, scissors, grease pencils, magnifying glass, duster, cleaning fluid, note pad and pencil.

Editing Procedure. Some 16 mm. and all 35 mm. users film with the negative-positive system. The first prints (or "rushes") made from the negative are projected as soon as possible, usually the day after shooting, and these are the positives that are handled in the cutting room in the building up of the cutting copy. Many narrow gauge users do their filming on reversal stock—in this case the editor should be given a reversal duplicate for cutting purposes in order to avoid the hazards of handling the original when doing the editing.

The editor has his own copy of the script. He is given a copy of the notes made by the director and copies of the continuity sheets prepared by the continuity assistant. During the showing of the rushes to the key members of the unit he also makes his own notes. He will thus know which are the best takes and will have noted any inferior sections which should be avoided if possible.

First the rolls of positive as received from the laboratory are broken down and the separate scenes are sorted out in numerical order to match the script. With the aid of his notes the editor immediately extracts the unwanted and faulty material. What remains is then joined into reels in script order and projected as a check that all the essential material for the film is there. If there is a sound track each reel will consist of two rolls—separate picture and sound.

Then follows the rough-cut stage when all obviously unnecessary portions of the good takes are cut out—such as number boards, excess action and mistakes—and the material is arranged in a much condensed form that begins to resemble the film as it will finally be.

After approval from producer and director and with their suggestions, the editor then settles down to finer cutting, an operation in which he exercises his freedom of choice in the detailed consideration of the cuts from shot to shot. This process may last quite a long time and is a vital stage with continual experimenting to achieve just the right timings and general effects.

The sound, whether synchronized at the moment of filming or soon afterwards at a post-recording session, is whenever possible edited at the same time as the picture. Sound makes the work of editing more complex, but the specialized equipment helps to overcome the extra difficulties. The 35 mm. editor runs his lengths of film through a viewer or editing machine which not only shows a small animated picture but reproduces the sound from the sound track in synchronism. The narrow-gauge worker may use a specially adapted version of the 35 mm. editing machine, but in general most of his sound editing must be carried out on the sound projector.

In all but the most unpretentious films the next step will be the fitting of music and sound effects to the picture and the process of re-recording them with the existing sound track all on to one track.

After that the negatives or originals will be cut to match the cutting copy and a final print produced that has the sound and picture printed on to the same strip of film.

Silent films are naturally the easiest proposition. The amateur, especially, is not involved in such intense activity as the professional and his apparatus is simpler, but in principle his editing will conform to the same rules if he takes his film making seriously. When the fine-cut stage has been completed the main task that remains for him is to add the titles.

Editing Principles. The creative side of editing is one aspect of the expression of cinematographic art. While a number of principles have become established, largely by trial and error, as a sound basis for editing practice, they are guides rather than firm rules.

The art of editing in the main deals with continuity, timing and the creation of filmic relationships.

In its simplest terms continuity is concerned with keeping the film flowing smoothly without disturbing jumps or gaps.

Firstly, the editor has to choose the different types of shot available of a scene. Thus a long shot introduces the subject, while medium and close shots following after draw attention to specific details. The continuity of action depends also on the camera direction in a sequence. Thus when the camera moves in on a scene, the different shots should be from different viewpoints to avoid sudden jumps. Where such jumps are unavoidable, they can often be bridged by a cut-away—a shot of a different but related part of the subject.

Where the same action takes place in, say, a medium shot and a close shot, the two must be matched in joining, so that the action continues smoothly from the one to the other.

Cross-cutting or inter-cutting is a technique of linking two related and parallel actions in a film and incidentally also of heightening tension. The classic example is the rescue theme involving two basic sequences: the victim awaiting his or her end at the hands of the villain, and the rescuer hurrying to the scene. For cross-cutting the two shots are split up into short lengths and joined up alternately. The cross-cut part-shots are made progressively shorter and shorter to build up to the climax.

This is one of many aspects also of timing. Quite apart from the speed of movement of the subject in the film, the length of a shot conveys the rate of action. The shorter a shot appears on the screen, the faster the tempo or illusion of speed conveyed. Thus the impression of action can be derived from a rapid succession of very

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

short shots without any significant inherent motion. Thus a flashing succession of newspaper headlines can suggest fast-moving events.

Inter-cutting can also stretch the length of an action. Thus a sequence of an accident lasting only a few seconds can be made to occupy two or three times its length in screen time by inter-cutting the event itself with the reactions of victims, onlookers, etc.

Conversely, editing can also compress time. For example if the story involves a trans-atlantic journey, a shot of the boat leaving the English port (established in previous shots) cut to the same boat with the Statue of Liberty in the background, tells the audience that the journey has taken place, without showing any of it in detail. Dissolves and fades are also classical means of bridging both space and time.

On a smaller scale the lapse of time—for example to eliminate a familiar and not particularly interesting action like dressing—can be bridged by a cut-away shot. In this case a close-up of a clock would do, and might also establish that the character is in a hurry.

The power of suggestion by the juxtaposition of seemingly unrelated shots to create a relationship is a further important tool of editing. Thus a shot of a character looking out of the window (filmed in the studio) followed by a scene of a cheering crowd taken from a newsreel conveys the impression that the character is watching the crowd.

Even the order in which the two shots are presented can give a different interpretation to the story: if the actor is seen first and the cheering crowd afterwards, the inference is that the crowd is cheering the hero. If the crowd shot precedes the actor, he may be taken to be a mere spectator. Similarly, shots of a burning model building, intercut with a racing fire engine and studio shots of rushing firemen, build up the story of a big fire.

While editing sound films is more complex, the scope of creative editing is greater still. Here sound effects can be added to the picture to create straightforward or contrasting relationships. They can also bridge visual points which would otherwise have to be linked by additional shots to preserve the continuity.

EDUCATION

EDUCATION. There are two and fundamentally different aspects of photographic education: on the one hand the use of photography as an educational aid, and the other the training of photographers.

Education with Photography. The application of photographic images to education covers cine films, and still films in the form of film strips and slides, as well as individual prints.

Cine films are available as specially planned films for class room showing with the aid of 8 mm. or 16 mm. projectors. Most of these are comparatively short but self-contained features, and are produced and planned as complete items covering a selected subject, being screened in the class room—usually after blacking-out—as part of a lecture or a complete lecture. Such films may run from ten minutes to half an hour in length and illustrate a subject, usually together with a commentary or other sound effects. In the 16 mm. gauge such films are generally mass produced and sold or hired to schools and other institutes.

Much the same applies to 8 mm. films, but there are two additional possibilities. The first is the production of the film by a teacher or a group of teachers. Here 8 mm. film has the advantage of cheapness both in material and in the camera equipment required. In most cases teacher-produced films are likely to cover mainly travel scenes, etc., though occasionally more ambitious projects may be handled. This is largely a matter of the cinematographic experience and skill of the teacher concerned.

The second possibility is the short and ultra-short concept film. Here single ideas are presented in filmic form, running on the average no more than two minutes. Such films may be shown on more or less frequent occasions in the course of a lecture. Their presentation involves special apparatus and systems, to permit immediate projection at any selected moment, much like drawing a diagram on a blackboard. Only the film can convey a moving idea—which may be either realistic or diagrammatic. Such concept films are generally mass-produced, and may be obtained by hire or purchase from suitable libraries.

Still pictures may be presented as film strips or slides. Film strips are available as self-contained series, sometimes with recorded tapes giving explanations and commentaries which may be played on tape recorders combined or linked with the film strip projector. Signals on the tape can be used to advance the projector automatically from one image to the next at the appropriate points in the narration. Slides are more flexible for presenting individual items, but here again a complete series may be linked with a recorded tape commentary.

Individual illustrations in the form of large transparencies can also be shown with overhead projectors. This has the advantage that the teacher or instructor can even draw diagrams on a transparent foil in the overhead projector, for presentation to the whole class in much the same way as on the blackboard.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Episcope projection of opaque illustrations (photographs, pictures from books, etc.) is less popular nowadays, mainly because the brightness of an episcope image is usually limited.

Education for Photography. Polytechnics and departments of technical colleges in Britain provide training courses for professional photographers. Usually they aim at preparing pupils for the IIP or City and Guilds examinations, which are regarded as standard qualifications for a photographer. In various countries in Europe there are special schools of technical college standard devoted entirely to photography.

All these schools and courses produce qualified practical photographers, and therefore provide instruction both in photographic theory and in actual picture taking. There are also courses at a number of institutes in Europe for theoretical photography. These are concerned with the academic training of photographic scientists and technicians, and lead to Ph.D. and similar degrees.

EFFLORESCENCE. Process by which a crystalline substance gives up its water of crystallization to the air and turns into the amorphous, powdery state. The white dust that forms on crystals of sodium carbonate (washing soda) when exposed to the air is an instance of efflorescence.

EIKONOGEN. Sodium 1-amino-2-naphthol-6-sulphonate. Developing agent. Now little used for that purpose.

Formula and molecular weight: $NH_2C_{10}H_5OHSO_3Na$; 261.

Characteristics: White powder. Somewhat resembles metol in its developing action.

Solubility: Slightly soluble in water at room temperature.

ELECTRIC CHARGES ON FILMS. The surface friction produced by handling or unrolling films may build up a charge of static electricity sufficient to create a spark or a visible glow discharge. This discharge is sometimes (but not often) intense enough to form a developable image on the film.

See also: *Static.*

ELECTRIC EYE. Common term, especially in advertising literature, for automatic exposure meter systems which directly control the lens aperture (and sometimes also the shutter speed setting) in response to the light falling on a photo cell.

See also: *Exposure automation.*

ELECTRICITY. Nowadays electricity is used in practically every department of photography—taking the photograph, processing the negative, and making the print or enlargement.

Most of the electricity used in these ways is for lighting; the remainder is for heating and for driving motors. The electricity supplied for all these purposes may be direct or alternating and its voltage may be around 110 volts or anywhere between 200 and 250 volts. The chances are, however, that it will be alternating current of 240 volts and a frequency of 50 cycles per second. This supply is gradually replacing all others throughout the British Isles. The standard American household supply is 115 volt, 60 cycle alternating current.

Changes or additions to the permanent wiring of buildings should preferably be made by a qualified electrical contractor. Any handyman who proposes to do the job himself should first study the relevant I.E.E. regulations on the subject. Copies of the rules applying to the particular job—e.g., permanent wiring, flexible cords, fuses—can usually be obtained from the local office of the British Electricity Authority or by application direct to the Institute of Electrical Engineers.

Equipment Circuits. There are two ways of connecting a number of pieces of equipment to an electricity supply—in series and in parallel.

When pieces of equipment are connected in series end-to-end, all the separate resistances of each item add together and their sum is the total resistance that the circuit offers to the flow of electricity from the supply. So ten pieces of the same kind of equipment offer ten times more resistance to the flow of electricity than a single piece of that equipment.

And the current that flows through the ten connected in series is exactly one tenth of the current that would flow if only one piece of equipment were there.

In the same way, two lamps connected in series pass only half as much current as one connected to the supply by itself. And since the voltage is the same in each case, the two lamps together consume only half as much electricity as one. But, of course, the amount of light is also greatly reduced.

When pieces of equipment are connected in parallel—i.e., side-by-side—each piece of equipment has the full voltage of the supply acting on it. So each separate item acts as though the others were not there. Each takes its full quota of current from the supply. So ten pieces of the same sort of equipment connected in parallel across the same supply take ten times more current than one. And the effective resistance of the whole circuit is one tenth of the resistance of a single item.

The general rule is expressed by the equation:

$$\frac{1}{R} = \frac{1}{r_1} + \frac{1}{r_2} + \frac{1}{r_3} + \text{etc.}$$

where R is the total effective resistance of the circuit and r_1, r_2, r_3 etc., are the separate resistances of each individual item.

Cells in Series and Parallel. When a number of cells are connected in series, end-to-end, the positive of one cell to the negative of the next, their combined voltage is equal to the sum of

CC-0. Agamnigam Digital Preservation Foundation Chennai

SERIES AND PARALLEL CONNEXION. Top: Three lamps in parallel. Centre: Lamps in series. Bottom: Two batteries in parallel, each with four cells in series.

the separate voltages. Ten 1·5-volt cells in series have a combined voltage of 10 × 1·5 = 15 volts.

The actual amount of the current that can be delivered by a cell is limited by its internal resistance, so that the current that can be delivered by a number of cells in series will be no greater than the current that can be delivered by a single cell.

When a number of cells are connected in parallel, with all the positive terminals connected together as one pole, and all the negatives as the other, the effect is exactly the same as if all the separate cells were merged into one. So ten 1·5-volt cells connected in parallel become one big cell, and the voltage remains unaltered at 1·5 volts.

Connected in this way each cell is still capable of delivering its full current, limited only by its internal resistance. So the ten cells in parallel are able to deliver ten times as much current as a single cell.

When cells are connected in series they give a higher voltage; in parallel, they deliver a higher current. There is a third type of circuit that gives an increase in both voltage and current. This method of connecting the cells is called series-parallel, and it is a combination of the other two.

Four 1·5-volt cells can be connected in series to make a 6-volt battery, and if they cannot deliver enough current for their purpose, an identical battery of four 1·5-volt cells can be connected in parallel with the first. The second battery will double the current available while the voltage will still be only 6 volts. This is an example of series-parallel connexion as it is often used for boosting batteries to supply extra flash bulbs on the same circuit.

The behaviour of cells in series and parallel is of great importance in photography with flash bulbs where a flash bulb that takes a relatively heavy current operates from small portable batteries. Delay or failure of the flash through weak batteries can be a very serious matter to the photographer.

Basic Calculations. The electrical units are interdependent, e.g., an electrical pressure of 1 volt applied to a circuit with a resistance of 1 ohm would send a current of 1 amp through the circuit.

The rate of power consumption in a circuit is given by the relationship:

$$\text{watts} = \text{volts} \times \text{amps}.$$

For instance, on a 250-volt mains supply, a lamp carrying 0·8 amps would consume 250 × 0·8 = 200 watts. The amount of electricity that would have to be paid for if this current were switched on for, say, 2,000 hours is given by the relationship:

$$\text{Kilowatt hours (units)} = \frac{\text{watts} \times \text{time (in hours)}}{1{,}000}$$

$$\text{or, in this case } \frac{200 \times 2{,}000}{1{,}000} = 400 \text{ units}$$

The relationship between volts, amps, and ohms, is usually expressed by the formula known as Ohm's Law:—

$$\text{Current in the circuit(C)} = \frac{\text{E(Voltage of the supply)}}{\text{R(Resistance of the circuit)}}$$

So if any two of these factors are known, the third can be found immediately.

For example if, say, a Photoflood lamp with a resistance of 190 ohms is connected to the 230 volt supply, the current that will flow in the lamp wiring will be:

$$\text{Current} = \frac{230}{190} = 1{\cdot}2 \text{ amps.}$$

The watts consumed by such a lamp will be: watts = volts × amps. = 230 × 1·2 = 275.

If such a lamp has a life of 2 hours, it will consume altogether 2 × 275, or 0·550 kilowatt hours, or units of electricity, i.e., just over half a unit while it lasts. F.P.

ELECTROLUMINESCENCE. Direct conversion of electrical energy into visible light (instead of for example as a by-product of the heating effect of passing a current through a tungsten filament). A substance exhibiting electro-luminescence glows when subjected to an A.C. electric field.

The most promising electroluminescent substances to date are phosphorescent substances

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

like zinc sulphide—closely related to the screen phosphors in cathode ray tubes.

The phosphor is distributed in an extremely fine powdered state over the surface of a base of metal or conducting glass. It may be suspended in a synthetic resin or a transparent vitreous enamel. A layer of conducting glass, resin or enamel, is applied over the phosphor. A final coat of transparent and electrically insulating enamel protects the surface and makes it safe to handle. When a voltage is applied to the outer conducting layers of the sandwich, the phosphor glows. The voltage required to produce luminescence varies according to the method and materials of construction, but may be anything from 50 to several thousand volts. The colour varies according to the phosphor used and the light output increases with frequency of the exciting current. A typical electroluminescent panel run at 350 volts and 400 c.p.s. gives a luminance of 22 feet-lamberts for a current consumption of 1.5 mA. per sq. in.

Photographic Applications. The soft green light emitted by the normal electroluminescent panel makes an excellent safelight for darkrooms where panchromatic films are handled. Electroluminescent lighting is used for darkroom clock faces, wall switch surrounds, instrument dials and pointers.

Photo-sensitive panels. A number of interesting and useful possibilities result from the combination of an electroluminescent layer with one that is photoconductive—i.e. that changes from an insulator to a conductor when light falls on it. When the two layers are sandwiched together between layers of electrically conducting glass carrying a sufficiently high voltage, a light directed on to the photosensitive layer causes it to conduct the electrical charge at that point. The electroluminescent layer is subjected to a voltage at that point and it glows. Even when the initial light is switched off, the glow from the electroluminescent layer continues to maintain the conductivity of the photosensitive layer, so the glow persists until the applied voltage is switched off. This basic phenomenon can be exploited in several ways:

1. *Image Intensification.* By adjusting the characteristics of the two layers, the light falling on the photosensitive layer can be made to excite a glow of greater brilliance in the electroluminescent layer. The combination will then act as an image intensifier.

2. *Image Converter.* The photosensitive layer can be made to respond to non-visible radiant energy—e.g. X-rays, ultra-violet or infra-red. The combination will then act as an image converter, turning an invisible image into one that can be seen.

3. *Image Storage Device.* Because the glow from the electroluminescent layer continues to excite the photoconductive layer in the areas of brightness even when the original image-forming rays are switched off, the panel will act as an image storage device that can hold the picture of transient phenomena as long as the applied voltage is maintained. Once the voltage is switched off the luminous glow disappears and the panel is ready to accept another image. In this way an electroluminescent panel can perform many of the functions of a photographic plate which needs neither developing nor fixing and can be re-used indefinitely. F.P.

See also: *Fluorescent lamp.*

ELECTRO-LUMINESCENT PANEL. A, transparent layer of conducting glass. B, photo-conductive layer. C, electro-luminescent phosphor layer. D, metal or conducting glass support plate. A voltage is applied across the top and bottom layers and causes the phosphor layer to glow. If a D.C. voltage is applied, the panel only glows when light falls on it and can in this form be used as an image intensifier, and a short-term image retaining system.

ELECTROLYTIC DEVELOPMENT. System of processing a photographic image by the application of an electric voltage or field.

In photographic systems based on the use of silver salts, the essential step in image development is the deposition of silver. This is so even if the ultimate pigment is to be something other than silver, e.g., a dye.

In order to reduce silver salts to silver metal, it is necessary to donate an electron to each silver ion. In conventional developers, the source of electrons is the developing agent, usually an organic compound which, on giving up electrons, can pass into another, more stable, form. Since, therefore, the fundamental process involves the passage of electric current, it is possible to use electricity, more or less directly to carry out development.

So-called electrolytic development can be divided into two main categories; (a) generation of a developer by electrolysis, and (b) photoconductive systems.

Electrolysis. The first category applies to the development of conventional materials carrying an emulsion layer in which grains of silver halide are embedded in gelatin. Here the problem is one of application of the electrical energy available at a massive electrode to the latent image in each grain. The only practicable method is to use the electrical energy to generate a solution of low redox potential, i.e., a solution capable of reducing silver halides. It is this solution which diffuses into the emulsion layer and carries out the development along conventional lines. The electrolysis serves only to generate the reducing solution in the first instance and to regenerate it as it is used. It has

CC-0. Ramnigan Digital Presentation Foundation Chennai

been claimed that an image can be developed simply by placing an exposed layer in contact with a cathode in water, but this must have depended on the generation of some reducing agent, e.g., nascent hydrogen.

The nearest approach to a practicable system was produced by Roman who electrolysed a solution of a vanadium salt in hydrobromic acid. A solution of vanadous ion was formed in the cathode compartment and this solution could be pumped to the developing tank from which it returned for regeneration. The system could be used for the development of motion picture positive film.

Photoconductive Systems. These are of more interest at the present time inasmuch as they are adaptable to various processes for the recording and reproduction of information. In these systems the light image is converted in effect into an electrical image. In one form, a zinc oxide photoconductive emulsion is coated on a metallic support. After the xerographic exposure the layer carries a pattern of varying conductivity. This layer is wiped with a silver-bearing solution while a potential is applied between the wiping device and the metallic under-layer, the latter being the cathode. The local conductivity determines the intensity of the local current and, hence, the amount of silver deposited. In this way a silver image is built up electrolytically on the "conductivity image".

In another form, due to Berchtold, a sheet is made by cutting a slice from a bundle of innumerable, fine wires that are bonded together, but insulated from each other, by a resin. Such a sheet is highly conductive from front to rear but is a non-conductor sideways. A photoconductive (selenium) layer is coated on one side of the Berchtold sheet and a thin, transparent metal film is coated over the selenium to act as a contact. A wet, electrosensitive paper, which can carry a silver salt or a dye, is pressed against the rear side of the Berchtold layer by means of a conducting plate. If a voltage is applied between the front and rear contacts of the assembly while an image is thrown on the selenium layer, the electrosensitive paper will be affected by the current in contact with the micro-electrodes. The photosensitive part of the process is not expendable and can be used indefinitely.

Currently electrolytic systems of this kind are finding applications in document copying.

ELECTRONIC FLASH. Light source which utilizes the short duration flash of light produced by discharging a medium or high-voltage charge through a gas-filled tube.

See also: *Flash (electronic).*

ELECTRONIC PRINTING

Method of making photographic contact prints and enlargements with a flying spot scanner instead of a continuous light source. An electron beam moves over the fluorescent face plate of a cathode ray tube in a regular pattern; the light spot produced exposes the negative point by point on to the printing paper. The main advantage over a continuous light source is that the light coming through the negative can be monitored continuously by a photo cell which can in turn influence the brightness of the light spot. That provides considerable scope for contrast control.

Photo-multiplier Monitoring. In electronic printing equipment the cathode ray tube is in virtually direct contact with the negative being printed. In a contact printer the positive material is in contact with the negative and a photo-multiplier tube records the light coming through the positive material.

In an electronic enlarger the cathode ray tube is in contact with the negative in the negative carrier. The enlarger lens there projects the image on to the printing paper on the enlarger baseboard in the usual way. The monitoring tube can again monitor the light coming through the printing paper; the more usual system is to have a beam splitter just below or just above the enlarger lens to divert a fraction of the light (about 5 per cent) to the photo tube.

In either case the photo-multiplier tube controls the intensity of the scanning spot and in this way the contrast of the resulting print. For this purpose the output of the photo-multiplier is fed into an inverse feed-back amplifier.

The feed-back amplifier is linked with the circuits controlling the intensity of the electron beam. When the photo tube registers a high light intensity (as the electron beam scans thin parts of the negative) the feed-back circuit reduces the intensity of the scanning spot. Hence thin parts receive less exposure than they would otherwise do. Conversely, when the photo tube output drops, the feed-back amplifier increases the intensity of the electron beam so that dense parts of the negative receive more exposure. So what takes place is an automatic and simultaneous shading and overprinting of various parts of the negative according to their densities. This reduces the contrast of the print, so that even negatives of extreme tone range can yield acceptable prints on a normal or even hard grade of paper.

Put in another way, the negative is printed with a light source that corresponds to a luminous positive image. This takes over all the functions of an unsharp positive mask produced by conventional printing procedures, except that the light mask is formed automatically during the printing process and requires no preparatory work or processing. It is also auto-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

ELECTRONIC ENLARGER SYSTEM: A, cathode ray tube with flying spot scanner. B, negative. C, beam-splitting mirror. D, control of cathode ray tube. E, inverse feedback amplifier. F, contrast control adjustment (by feedback setting). G, monitoring photo tube. By additional control circuits this can also regulate the overall exposure by suitable brightness control of the flying spot.

matically related to the negative and in register with it.

Adjusting the feed-back of the amplifier controls both the mask density and contrast. If the feed-back is set to zero, the printing effect is the same as with a continuous light source: the scanning spot remains uniformly bright throughout the exposure.

Negative feed-back, as just explained, increases the scanning spot brightness when scanning dense negative areas and decreases it for thin negative areas. With 100 per cent negative feed-back the increases and decreases just compensate the negative densities; in theory this should give a completely uniform print density with no recognizable image. (In practice image outlines do remain visible owing to fringe effects, as explained below.)

The feed-back can also be made positive, so that the scanning spot gets brighter when the photo tube receives a lot of light through thin negative areas, and less intense when scanning denser areas. This would increase the contrast of the print; electronic printing thus provides a virtually unlimited degree of contrast control. In practice, electronic enlargers can handle negative density ranges up to about 3·0 and compress these to a range of 0·1 to 0·3 on a print. Even when a negative density range of 3·0 is reduced to 1·0 on the print, this corresponds to accommodating a subject brightness range of 1,000 : 1 (assuming a negative gamma of 1·0) within a print brightness range of 10 : 1.

Contrast Range and Detail Contrast. In theory a similar compression of brightness range would be possible by printing a contrasty negative on an extremely soft gradation paper. This would compress all tones uniformly and would equally reduce the detail contrast to an unnatural degree. The resulting print looks soft, even though it may have a full tone range from white to black.

Electronic printing gets over the difficulty by compressing the overall contrast without modifying the detail contrast to the same extent. The two can in fact be adjusted independently. This is important because a compressed tone range in a print where detail contrast is compressed along with overall contrast may make some detail invisible. Tone differences above the threshold of differentiation in the original may drop below this in the print.

Electronic tone contrast control thus corresponds more to tone separation.

This is achieved by controlling the size of the scanning spot as well as the inverse feed-back. While the amount of feed-back determines the overall contrast compression (corresponding to the mask percentage in masking), the spot size determines the unsharpness (and hence detail control) of the mask. The printer does not compensate for brightness variations over areas smaller than the scanning spot itself. It therefore preserves detail contrast both within highlights and within shadows, even when the overall exposure in negative shadows is increased and in highlights decreased.

The scanning spot size is chosen (by appropriate focusing of the electron beam) according to the requirements of the negative. A negative of great contrast but comparatively little fine detail would be printed with a large spot size and appreciable feed-back. A negative of lower overall contrast but with a great deal of fine detail (for instance an aerial photograph) would need a small spot size and moderate feed-back. In practice, spot sizes are held between 1/16 and ¼ in.

Fringing. The finite size of the scanning spot also leads to the fringing effect which is characteristic of electronic printing with a moving spot. As the spot scans a boundary of the image from light to dark, the light reaching the monitoring photo tube does not change suddenly but gradually. With the spot half way across the boundary, the light falling on the photo tube is half-way between that for the bright and for the dark areas. As however the feed-back circuit reacts instantly, the boundary of the shadow area begins to receive more exposure than the shadow region just traversed by the spot. Similarly the edge of the highlight area gets less exposure than the region covered by the spot immediately afterwards. This leads to a dark fringe at the border of the shadow area in the print and a light fringe at the border of the highlight area (where it is particularly noticeable). The width of the fringe depends on the time the spot takes to cross the boundary; with a fixed scanning speed it is greater the larger the spot.

CC-0. Agamnigam Digital Preservation Foundation (Chandigarh)

THE FRINGE EFFECT. When the scanning spot of the cathode ray tube moves from a dark shadow area to a light one (top), the feedback causes the spot brightness to drop gradually owing to the finite spot size (bottom left). The print density PD as a result decreases at the border of a light area, and increases at the border of a dark one. The smaller the scanning spot, the less the fringe effect, but the lower the detail contrast.

Scanning and Exposure. The actual scanning pattern that the flying spot traverses is not particularly important, provided all parts of the negative area are covered by the spot for the same time during a complete scanning cycle. The scanning pattern itself may either be a line scan (as in a television receiver) or an interlaced diagonal one. The total scanning cycle may last from 1/10 second to several seconds; one scanning cycle is the minimum exposure for a print.

The exposure control may be combined with the contrast control or it may be separate. In the first case the monitoring photo-multiplier tube automatically adjusts the brightness of the flying spot so as to yield a correct exposure for every part of the print during one scanning cycle (or a fixed number of complete cycles). Every exposure takes the same length of time and negatives of different density are compensated by appropriate changes in the spot intensity. The electronic printer then needs setting only to the paper sensitivity.

Instruments with separate control use a second photo-multiplier tube which automatically terminates the exposure after a predetermined amount of light has reached the tube. The exposure itself must then last for a whole number of scanning cycles. Alternatively the brightness range of the projected image on the baseboard can be measured by photo tubes before the exposure itself. These measurements establish the brightest highlight and darkest shadow tones and are then used to set both the required contrast control and the actual exposure on the control unit for the printer.

Electronic Colour Printers. The same principle can be used for producing colour prints from colour negatives. The negatives are printed by three successive exposures through a red, green and blue tri-colour filter. During each filter exposure the photo tube monitors the light through a complementary filter (i.e. cyan, magenta and yellow respectively). The photo tube output is in turn connected to three inverse feed-back amplifiers for the three printing colours. These are linked with three timers which control the individual printing exposures. The output of the monitoring photo tube provides automatic colour correction during each exposure. By appropriate adjustment of the control circuits any degree of over-riding colour correction can also be applied.

A similar arrangement is used for making colour separation positives from separation negatives, or for making separation negatives from colour transparencies. In the first case the negative and the printing material are changed between each exposure; in the second case the colour transparency remains in position but the three exposures are made on separate films. The inverse feed-back can then function both for automatic contrast masking and for colour masking. Colour masking is achieved by monitoring the flying spot through a non-complementary filter. For example, to correct the unwanted blue absorption of cyan dyes, the red filter exposure can be monitored through a yellow filter.

This use of an electronic printing system is mainly confined to graphic arts applications (where separation negatives are still employed almost exclusively). For this purpose there are also a number a more elaborate arrangements for complete colour correction in making separation positives from negatives. For

ELECTRONIC COLOUR PRINTING. An enlarger with a flying spot scanner tube can be adapted to colour printing by monitoring the light through complementary filters (C, M, Y—cyan, magenta and yellow), while the printing exposure takes place through the primary tricolour filters (R, G, B—red, green, blue). A, flying spot scanner tube. D, negative. E, complementary monitoring filters. F, beam-splitter mirror. H, printing filters. J, photometer probes for measuring the density range (prior to the exposure). K, colour feedback amplifiers. L, monitoring photo tube. N, exposure timers. O, matching density scale. P, photometers for setting the timers.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

instance, in one electronic scanner all three separation negatives are scanned simultaneously by linked flying spots (or a single flying spot diverted to three negatives through beam splitters) while only one of the three negatives is being printed. The photo tubes that monitor the light coming through all three negatives (and hence react to colour errors recorded there) are then used to control the intensity of the flying spot which scans the negative actually being printed. In this way it is possible to introduce any degree of automatic colour masking and correction.

Applications. In the beginning electronic printers were developed for military purposes, especially the printing of aerial photographs. Such photographs have to be reproduced with maximum detail resolution, while the printing may require appreciable contrast control. Electronic printers prove equally useful in printing medical radiographs, where again the original image frequently requires considerable tone control to bring out the maximum significant detail. Electronic enlargers are widely used also in commercial photography.

The other main use of electronic printing equipment is in the graphic arts field, especially for colour correction and automatic masking. The electronic printer with its built-in masking control there saves appreciable operating time previously taken up with making masks in the conventional manner. Printing systems based on similar principles have also found their way into photo finishing printers and enlargers, and printing of motion picture positives in special fields.

ELECTRON MICROGRAPHY. Technique for recording photographically images formed by electrons in an electron microscope.

An electron microscope produces images by essentially the same process as the light microscope. However, the glass lenses in the latter are replaced by electromagnetic or electrostatic lenses (i.e. fields) and an electron beam provides the illumination. In an electron microscope electrons emitted from a heated tungsten filament are accelerated to a high velocity in an electric field of 50–100 kV. There are three "lenses" or fields: a condenser, an objective, and a projector lens. The condenser lens converges the electron beams on to the specimen which is placed just above the objective lens. Specimens are normally mounted on a metal grid containing numerous apertures approximately 70μ square. A greatly enlarged image is formed by the combination of objective and projector lenses, the precise magnification being controlled by the current passing through the projector lens. The enlarged electron image excites a fluorescent screen (used for visual examination); below is a camera system for recording the image photographically. The interior of the microscope is highly evacuated to avoid scatter of the electrons by collision with gas molecules.

Controls are available for precise alignment of the illuminating system and lenses, while both specimen and camera airlocks are fitted to save time when changing the specimen or photographic material. Provision is made for scanning the specimen for location of features of interest.

The major advantage of electronmicroscopy over light microscopy is the increased resolution. Whereas a resolution of 2,000 Å (about $\frac{1}{3}$ the wavelength of yellow light) is obtainable with a good light microscope, a figure of 5 to 10 Å is possible with most high-performance electron microscopes. This represents a useful magnification of one to two million times. The resolution obtained by no means represents the theoretical limit. This is not attained owing to aberrations in the lenses, primarily the objective, and the residual small instability in both high-voltage and lens current supplies.

Preparing Specimens. However good the microscope, for micrographs of high resolution the specimen must be thin enough to transmit a large fraction of the incident electrons without causing major changes in their velocity and direction. The specimen must also be stable and not contaminated at an excessive rate by the action of electrons on hydrocarbons present in the microscope system.

Methods of preparing suitable specimens vary according to the type of material and the nature of the examination to be made.

Microscopic particles are deposited on a very thin film of plastic (e.g. formvar or collodion), evaporated carbon or certain other inorganic materials and are viewed by direct transmission. This shows up shape, size and degree of aggregation of the particles (e.g., photographic emulsion grains, powders, virus particles).

Information on surface details of bulk material and microscopic particles (e.g. glass, fibres, metal surfaces) is obtained by replication. This involves coating a thin film of plastic, evaporated carbon or certain other inorganic materials directly on to the surface to be examined. The replica is removed either by stripping or by dissolving the specimen. It is then examined by direct transmission.

The microstructure of certain tissues and other bulk material can be conveniently studied by cutting ultra thin sections, the order of 200–600 Å thick, and viewing by direct transmission.

Many types of crystallographic material especially metals, may be examined by transmission, the specimen consisting of an ultra thin film produced by electropolishing or

ELECTRON MICROSCOPE. An electron beam is focused through the specimen and the image projected in stages up to a fluorescent screen for observation, or a film for photography. Magnetic coils control the electron beam and so act as lenses in much the same way in which glass elements control a light beam. A, electron source. B, condenser lens. C, specimen. D, objective lens. E, intermediate image. F, projector lens. G, final image. H, fluorescent screen or photographic film.

chemical etching. Such specimens are more typical of the original bulk material than cut sections since incorporation of structural disorder, or the disturbance of existing disorder, is kept to a minimum.

Further information on the character of a specimen is frequently obtained by shadowing. This is the oblique deposition of a layer of material 10–30 Å thick having a high density to electrons (e.g. platinum/palladium and gold/palladium alloys) on to the specimen by evaporation from a source. Raised areas of the specimen shield adjacent areas in a direction away from the source. These "shadows" are more transparent to electrons than the remainder of the specimen, and from their shape and size and angle of shadowing deductions can be made concerning the size and shape of surface features or the thickness and shape of particles.

Frequently thin sections of biological or animal tissue give insufficient contrast in the electron image. This can be overcome by treatment with solutions of inorganic materials such as uranyl acetate or phosphotungstic acid which are absorbed or react to different degrees with various constituents of the specimen, thus increasing their electron absorption.

Photographic Technique. For normal photographic records the plate or film is exposed directly to the electron beam. If a ciné record is required the fluorescent screen is photographed with a camera, but lower resolution is obtained.

All photographic emulsions give satisfactory results when exposed to electrons. There is a close correlation between speed to electrons and blue light, but not for white light since spectral sensitization is not operative in electron exposures. For most record purposes the fine grain process or lantern slide emulsions developed for recommended times in conventional MQ developers give the best compromise between speed and granularity.

Exposures must be correct; they are manually timed by raising and lowering the fluorescent screen, and range from 2 to 30 seconds.

Special Techniques. There are many other specialized techniques, e.g. the taking of stereoscopic pairs, the use of dark field microscopy and the recording of surface reflection micrographs. Some studies involve the use of special stages which enable the specimen to be heated, cooled, oriented or strained.

The desire of biologists to examine living tissue and of the metallurgist to examine specimens more directly typical of the bulk material is stimulating the development of instruments employing high accelerating voltages e.g. 300 kV to 1 mV, which gives greater electron penetration. R.B.F. & F.S.J.

ELECTROPHOTOGRAPHY

Electrophotography comprises photographic processes in which the image is formed by a change in the electrical properties of the sensitive materials induced by the action of light. Photoconductivity is the basis for the electrophotographic processes in widespread use. In these processes, when the sensitive surface is exposed, the light-struck areas become conductive. If the surface has an electrical charge it is destroyed in the now photo-conductive areas, or if an electrical charge is applied after exposure, it is retained in the unexposed areas and not in the illuminated areas. Thus an invisible image is formed in which the shadows are represented by the charged and electrically resistant areas, and the highlights are represented by the uncharged and conductive areas. This invisible image is rendered visible by the attraction of developer to the charged area (direct-positive image) or by

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

repulsion of developer to the conductive-uncharged area (reverse image).

Electrophotography provides a rapid means of reproducing direct-positive, reverse, line or continuous tone images. The results compare favourably with ordinary photographs taken by conventional methods. The main electrophotographic systems are xerography, Electrofax and persistent internal polarization.

Xerography. This is a dry process originated by C. F. Carlson. It is the oldest method of electrophotography and has been in use for a number of years, progressing from hand processing through the separate stages to make offset masters, to completely mechanized machines for office copying.

In xerography, a metal plate with a thin coating of vitreous selenium is sensitized by passing it under a corona charger (an array of wires at a potential of several thousand volts). This charger covers the plate with a layer of positive electrical charges.

The plate sensitized in this fashion can be exposed in the camera or by any of the normal printing methods. Its sensitivity is similar to orthochromatic film with a speed of 2.0 ASA to tungsten illumination.

The image on the plate is developed by dusting the plate with a pigmented powder, called a toner. When the toner has the opposite electrical charge (negative, in this case) its particles are attracted only to the charged areas to form a direct positive photographic image of electrostatically-held powder. When the toner has the same charge (positive, in this case) it is repelled by the surface charge to the discharged areas to form a reversal powder image.

PRINCIPLE OF XEROGRAPHY. 1. A corona discharge from charging wires deposits a uniform electric charge on the surface of a selenium plate (or drum). 2. Exposure in the camera locally discharges the plate. 3. Treatment with fine powder reveals charged areas. 4. The plate is covered with paper and passed through the charging wires again. 5. This transfers the powder image from the plate to the paper. 6. Heat fuses the powder permanently into the paper support.

The most common method of applying the toner to a xerographic plate is in a two-component developer mixture of the fine toner powder and a spherical bead carrier. This mixture is cascaded over the selenium surface after exposure. The plate may also be developed by a cloud of toner powder.

A print is usually made by the electrostatic transfer of the powder image to a suitable substitute such as paper. This is done by placing a sheet of paper in contact with the powder image and passing both, with the paper uppermost, under a corona unit. Under those conditions the paper becomes charged and attracts the powder particles from the weakly-charged image areas on the plate. So the image simply transfers itself to the paper. The image can then be "fixed" by heating it until the fusible powder melts and adheres to the paper.

The resolution of the print is about 15 lines per mm. with cascade development and electrostatic transfer, but may be as high as 80 lines per mm. with powder cloud development and adhesive transfer.

Dielectric Paper. Another type of electrophotography utilizes a sensitive material of a photoconductive pigment dispersed in an insulating binder resin. A direct-printing electrophotographic paper is made by coating the mixture on paper. This paper can be charged, exposed, developed and fixed to produce a permanent print. The transfer step, necessary with a selenium plate, is obviated by use of this expendable medium.

The best known process of this type is called Electrofax.

Zinc oxide sensitized with dyes to extend its spectral response from the ultraviolet into the visible is commonly employed as the photoconductive pigment. A dye-sensitized Electrofax coating has a speed of about 2.0 ASA to tungsten light.

The coating is covered with a negative charge from a corona unit and exposed in the same fashion as the selenium plate in xerography. A technique devised for the development of zinc oxide paper employs a "magnetic brush". In this method of applying a toner-carrier mixture to the image surface, a magnetic iron powder is used as the carrier and the mixture manipulated with magnets to effect deposition of the toner. Another technique for use with pigment binder paper employs a toner dispersed in an insulating liquid such as a hydrocarbon or halogenated hydrocarbon. The sheet is immersed in the liquid and the fine toner particles are attracted to form the visible image. Fluid development is usually superior to carrier-toner in the develop-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ELECTRO-PHOTOGRAPHY ON PAPER. 1. Paper with a zinc oxide or other dielectric coating receives a uniform charge from charging wires. 2. Exposure in the camera locally discharges the paper surface. 3. On treatment with pigment powder the latter adheres only to the charged areas. 4. Heat fuses this powder image to the support.

ment of continuous-tone images and for high resolution.

Another electrophotographic process utilizes a zinc oxide binder coated on an aluminium substrate, and develops by electrolytic reduction the conduction pattern formed. No charge layer is used, but development is carried out by applying a voltage to the exposed sheet while it contacts a solution of reducible ions such as silver. The ions are reduced to the metal in the light-exposed and conductive areas to yield a visible black reversed image.

Electro-plastic Systems. In the photo-plastic process a charge pattern image is formed on a thermo-plastic surface coated on a photoconductive layer. This charge pattern produces a stress in the plastic and—if the latter is softened by heating—permanently deforms the plastic in a micro-pattern. Under suitable illumination, this pattern can be viewed or projected as a photographic image.

Automation and Applications. Automatic machines based on both the xerographic and Electrofax methods are in use for copying of documents and drawings.

Both the magnetic brush and the liquid development techniques are being utilized in Electrofax office copies.

The use of toners with the same electrical charge as the surface charge to obtain reversed images has also been automated. Thus, xerography and Electrofax are applied to the production of positive enlargements from negative microfilm. High-output Xerographic machines utilize a selenium-coated drum which rotates continuously. Various stages around its circumference correspond to the charging, exposing, developing, and transfer phases. With it xerographic prints (e.g. from microfilms) can be made on continuous paper web. The electrostatic electrophotographic process machines are used extensively in this type of retrieval from microfilm.

Transfer of the xerographic image to an offset paper master as a convenient method to make such masters by photographic means was one of the earliest applications of xerography. The zinc oxide binder surface of Electrofax paper can also be converted to an offset master. Chemical treatment of the surface after fusing renders the background hydrophilic while fused toner images remain ink-receptive. Organic photoconductors in binders coated on aluminium are charged, exposed, developed and fixed in the same manner as the Electrofax coatings and are converted to a master by dissolving the background to expose the aluminium base.

The xerographic process is further used in radiography. Xeroradiographic prints are made by exposing selenium plates to X-rays, developing in semi-automatic equipment and transferring the image to sheets. The Electrofax process has been applied to computer write-out by exposing the paper by contact with a thin-window cathode ray tube. The binder system has also been used to form photo-resists by dissolving away the non-image areas to expose a suitable substrate.

As the zinc oxide binder can be repeat-processed it is capable of being developed in many colours. Using colour-separation masters, multicoloured line map prints are made by repeating the printing procedure using different-coloured liquid developers.

Persistent Internal Polarization. The formation of an image with internal charge separation within the photosensitive film is another electrophotographic process. It has been studied in the U.S.A. where it is called persistent internal polarization (P.I.P.) and in the Soviet Union where the sensitive material is called a photoelectret. By appropriate techniques this process can be made to produce either a direct or reverse image. As the charge pattern is internal and not on the surface as in xerography and Electrofax, it is relatively little affected by the atmosphere.

Although the scientific work on electrophotography processes was carried out long before the introduction of xerography, the first successful process was made in 1948. Since then, new processes and especially new techniques of development have greatly expanded the applications into and beyond those of conventional photography. The fact that in the process the materials are not made light-sensitive until ready to be used offers a clear-cut advantage over the fogging reaction of silver halide system to stray radiation before use. The convenient electrophotographic printing procedures, coupled with their low cost, are thus extending beyond commercial copying, where they are essential. T.J.K.

ELECTROPLANE CAMERA. Special type of cine camera in which one component of the lens is made to vibrate backwards and forwards in such a way that the focus of the lens is constantly shifting from the near foreground to the distance. At the same time, the lighting of the scene is switched in synchronism so that it shines only on that plane on which the lens is focused. The result is to give an optical illusion of extreme depth of field when the final positive film is projected and viewed in the normal way.

ELECTROTYPE. Copy of a relief printing surface. A mould is cast in a plastic from the original plate and is then electroplated with a metal, usually copper. When a sufficiently thick coating has been deposited, it is stripped off the mould, the back is filled solid with type metal, and the resulting electrotype is then used in printing in the same way as the original.

See also: *Photomechanical reproduction.*

ELEMENT. Basic substance which cannot be separated into component parts of simpler form by chemical methods of analysis.

Also term applied to single component of a lens system.

See also: *Chemicals; Chemical symbols.*

EMBOSSING PRINTS. Method of recessing the picture area of a print and leaving a raised white border in imitation of the "plate-sunk" effect incidental to printing with some types of line block.

The print is made on a sheet of paper big enough to leave a broad white margin all round. A rectangle of card about 1/16 in. thick is then cut so that it exactly coincides with the image. This piece of card is then placed on the print so that it covers the picture and is held in place with a dab of rubber solution. The two are then turned over on to a level surface.

At this point it is necessary to have a suitable tool, such as a blunt bone paper knife or the smooth end of a fountain pen. With this tool, the back of the print is worked down over the edge of the card by sliding the tool around the border and gradually increasing the pressure. Presently the paper will have a raised rectangle in the centre corresponding to the card underneath. When the print is turned face up and the card is removed from the front, the image will appear to be sunk into the surface. This is the effect produced by the pressure of the engraved or etched plates used for printing line reproductions. It is an effective way of finishing small unmounted prints—e.g., for sending out as Christmas or birthday greeting cards—and it has the advantage of giving the paper extra rigidity.

When a lot of prints are to be embossed in this way it helps to make a jig—i.e., a cut-out card just big enough to take the print, stuck down on to another card with the "plate" fixed in position in the middle. The print then fits automatically into the right position without measurement or any risk of slipping.

EMBOSSING A PLATE MARK. 1. Place the print over a sheet of stiff cardboard of the right size. 2. Press along the edges of the card from the back of the print. 3. The shape of the card is now imprinted on the front. Bottom: Two pieces of card stuck to a common base will produce a convenient jig.

When prints are to be mounted, the mount itself can be plate marked in the same way before or after the print is stuck down. In this case there is no need to leave a white border round the print because the necessary margin can be allowed for on the mount.

EMERSON, PETER HENRY, 1856–1936. British photographer, born in Cuba of an American father and an English mother. Settled in 1869 in England. Became photographer, advocate of "naturalistic" photography, and apostle of "art based upon scientific principles"; wrote a textbook, *Naturalistic Photography* (1889). He was opposed to retouching and "composite negatives". Advocated platinotype and photogravure as reproduction processes; favoured a moderate amount of soft focus. In 1891 he renounced the beliefs for which he had fought since before 1880 and declared that "photography was not Art".

EMULSION. An emulsion consists of a stable mass of finely divided particles of a substance uniformly dispersed in a liquid in which they remain suspended without dissolving. Each particle of the suspended substance is surrounded by a cushioning film of liquid which prevents it from joining particles around it.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The sensitive coating on photographic plates and films is a suspension of finely divided grains of silver bromide in gelatin.

See also: *Emulsion making; Gelatin; Sensitized materials manufacture.*

EMULSION MAKING. The manufacture of photographic emulsions involves several separate stages, each of which can give rise to a wide range of properties. It is by careful selection and combination of the treatments given that photographic emulsions of apparently distinct character are derived.

Precipitation. The photosensitive component of an emulsion is the microcrystalline phase of silver halide. Since silver chloride and silver bromide are crystallographically similar and can form mixed crystals in any proportion, grains varying continuously from pure silver chloride to pure silver bromide are obtainable. Silver iodide has a different crystal structure and is therefore only partially miscible with silver bromide. Consequently the practical upper limit of iodide concentration in a silver iodobromide emulsion is about 6 molar per cent (6 molecules iodide to 94 molecules bromide). Sensitivity generally increases from pure silver chloride to silver iodobromide, corresponding in practice to contact positive papers and negative camera films respectively.

The silver halide is formed by double decomposition from silver nitrate and alkali halide, e.g.:

$$AgNO_3 + KBr = AgBr + KNO_3$$

The precipitation is made in the presence of gelatin which acts as a protective colloid and allows a suspension of microcrystals to be obtained.

Ripening. Immediately after precipitation, the crystals are normally extremely fine, and since sensitivity is dependent upon grain size an emulsion thus prepared would be very slow. The ripening process is designed to increase the size of the grains to the desired level. Since crystal growth takes place by deposition from solution, and silver halides are very insoluble in water, solvents are added to increase their solubility by complex formation. These solvents are usually excess alkali halide and/or ammonia, and they may also be present during precipitation. Since silver chloride is more soluble than, say, silver iodobromide, the rate of grain growth of the former will be faster for given solvent conditions. Alternatively, silver chloride will generally require mild ripening conditions and silver iodobromide more vigorous conditions.

As with other chemical reactions, ripening proceeds at a greater rate with increase in temperature and this, together with control of ripening period, is used to control the grain size. Other factors, e.g. gelatin concentration, may also influence the course of ripening.

By the methods outlined above it is possible to arrive at emulsions of desired grain size characteristics, both with respect to mean grain size and spread of grain sizes. Thus a low speed, high contrast emulsion will require a narrow range of grain sizes with a small average, whereas a low contrast, high-speed emulsion will require the converse. Typical average grain diameters are, 0·1μ for positive emulsions, 0·3μ for high contrast "process" emulsions, 0·6μ for slow negative emulsions and up to 2μ for fast negative emulsions.

Washing. The salts left in solution after ripening (nitrate from precipitation and ripening solvents) can be harmful, particularly if present in sufficient quantity to crystallize out from the coated film. The emulsion is shredded after addition of gelatin to increase the concentration to 10–15 per cent and the soluble salts leached out by cold water. If the support is of paper, however, this may act as an absorbent for the salts and washing may not be required.

Digestion. Although to some extent the speed of the emulsion is determined by its grain size, it is obviously desirable to achieve maximum sensitivity of the grains. This is best done by heating the emulsions with a compound which is able to form silver sulphide specks at the grain surface. Such a compound may already be present as an impurity in the gelatin ("active" gelatin) or be deliberately added, e.g. sodium thiosulphate, thiourea (a few milligrams per kilogram of gelatin). Sensitivity first increases with time and then diminishes. Fog increases with time and an optimum point is reached when sufficient speed is obtained without excessive fog. This time is obviously dependent upon the temperature used and the concentration of sensitizer.

When maximum speed is desired, e.g. for high speed camera materials, use is made of gold sensitization. Small quantities of a complex gold salt (e.g. about 5 milligrams gold as ammonium aurothiocyanate per 100 grams silver nitrate) may be added before or after digestion. Such sensitization usually results in a reduction of contrast.

Stabilization. When the required sensitivity has been reached, the digestion process must be stopped. This is done by addition of a stabilizer which is usually a heterocyclic compound selected from certain classes, e.g. triazole, tetrazole, iminazole. Compounds of this type may also be used to control the tone of the image in silver chloride or silver chlorobromide emulsions.

Spectral Sensitivity. An emulsion prepared in the above manner has limited sensitivity, for example silver chloride is insensitive above about 400mμ, silver iodobromide about 500mμ. To extend this range optical sensitizers are used. These are dyes which stain the silver halide and are of such a type that the energy absorbed by them can be transferred to the crystal to form a latent image.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

By this means the emulsion may be sensitized over the whole spectrum (panchromatic emulsions) or selected parts of the spectrum (orthochromatic, infra-red, colour emulsions).

Other Aspects. The above procedures are followed for all develop-out materials, together with various methods of controlling the physical properties of the emulsion. The actual constitution of the coated layer may, however, be modified to suit the emulsion to its use. For instance, positive paper emulsions, being of inherently high contrast are coated at relatively low coating weights (1–2 grams silver per square metre) whereas negative camera emulsions are coated at 4–8 grams silver per square metre. X-ray emulsions, being of high speed, are coarse grained and therefore of low covering power. High contrast is achieved by ensuring uniformity of grain size and by use of high coating weighs (10–15 grams silver per square metre). For direct X-ray exposure speed increases with coating weight and consequently values as high as 30 grams silver per square metre may be used.

For recording of ionizing particles, nuclear emulsions are used which are characterized by their high stopping power. Here the emulsion may contain over 80 per cent by weight of silver halide and be coated with dry thickness exceeding 1 mm. (conventional emulsions 5–15μ).

If high resolution is required, not only must the emulsion be of uniform fine grain but the effect of light scatter within the emulsion layer must be reduced. This is done by use of a thin emulsion layer or by use of a filter dye within the emulsion.

Print-out Papers. These are generally of low sensitivity and are capable of producing sufficiently high density without development. This is obtained by using silver chloride as the sensitive phase together with a halogen acceptor to remove the liberated chlorine which would otherwise retard the photolysis. Such a halogen acceptor can be silver nitrate, silver citrate or sodium nitrite.

This review of the principles involved in emulsion making is of necessity brief and generalized. Modern emulsion making is a specialized technology and while publications exist which provide recipes, it is certain that the results from these will be inferior to those from commercially available products. R.E.W.

Books: *Making and Coating Photographic Emulsions*, by V. L. Zelikman and S. M. Levi (London). *Film Coating Theory*, by B. V. Deryagin and S. M. Levi (London).

EMULSION REMOVAL. It may be desirable to remove the gelatin film from some old glass negatives or lantern slides. The glass can then be used for lantern slide cover glasses, for holding down film negatives in printing frames or even, in the very large sizes, for glazing greenhouses or garden frames.

When the negatives are very old the film is not easy to remove, and it is even more difficult to do this if the negative has been coated with protective varnish. The procedure is then as follows. Soak the negatives or lantern plates in cold water. (It is easier to remove the film after soaking for several hours.) Transfer the negatives to the following solution, heated up to nearly boiling point:

Caustic soda	4 ounces	100 grams
Water	40 ounces	1,000 c.cm.

This will remove the films very rapidly but is very corrosive if splashed on the skin or clothes. Transfer the glass to cold water, wash and dry.

Another method: soak the plates for some hours in water. Take a plate and place emulsion side upwards in a large photographic dish filled with hot water. After about a minute, take another plate of the same size with smooth edges, and use this as a scraper held at 45° to remove the film. It is quite easy to do this without risk of scratching the glass. Wash and dry the glass.

When making lantern slides, the easiest way to recover the glass from any waste plates is to take them from the fixing bath and dry without washing. After the film has dried it is usually possible to pull the film off the glass. If it does not come away readily, a short soaking will remove it.

The type of household bleaching fluid incorporating stabilized electrolytic sodium hypochlorite sold in bottles for domestic cleaning, etc., is also excellent for removing the emulsion from negatives. The fluid is simply applied at full strength to the emulsion surface and in a few moments the emulsion can be rubbed off. Concentrated hydrochloric acid can be used in the same way, but the fingers should not be immersed in the solution for any length of time.

All the above methods apply equally both to plate and film negatives. Special emulsions are available which permit easy removal. R.M.F.

See also: *Stripping.*

EMULSION SURFACE TEST. The emulsion side of negatives can generally be recognized by the slightly duller appearance. The difference is less noticeable in hardened or scratch-proofed negatives, but films so treated tend to curl towards the emulsion side when the negative is held in the palm of the hand. And when the emulsion is viewed obliquely against the light, the image can often be seen standing out in relief.

When the film is held up to the light and the negative image appears the right way around, the emulsion surface is then facing away from the observer. So if the subject includes any lettering, e.g., shop signs, notices, the emulsion side can be recognized at once.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

There is no difficulty in recognizing the emulsion side of a plate negative because the difference between the gelatin and glass surfaces is generally obvious at once. If there is any doubt, the two sides should be touched in turn with the tip of the tongue; the emulsion side has an unmistakable tendency to stick.

The emulsion side of sheet-films also can be easily determined as all such material is notched. When a sheet is held so that the notch is at the top left-hand corner, then the emulsion side is facing away from the viewer.

Another way of finding out is to scratch the margin of the plate with a pin; only the emulsion side will scratch.

The emulsion side of most papers can be recognized by its sheen. Matt papers have very little sheen, but, like films, they tend to curl towards the emulsion side when laid on the palm of the hand. And if a corner of any paper is lightly bitten, the side that sticks to the teeth is the emulsion side.

ENAMEL AND CERAMIC PHOTOGRAPHS. There are various methods by which a photographic image may be made to appear permanently on a glazed porcelain surface. The principle is simple: the photographic silver image is replaced by an image consisting of a vitrifiable metallic oxide which will fire to the desired colour. This image is transferred to the unglazed pottery and thereafter the normal kilning and glazing proceeds as usual. Pictures applied in this way are absolutely permanent.

See also: *Ceramics; Dusting-on process; Printing on special supports.*

ENCAUSTIC PASTE. Mixture of roughly equal parts of white wax and oil of turpentine with half a part of dammar varnish, applied to the surface of a print (on rough or matt paper) to add depth to the shadows. The paste kills the "bloom" veiling the black areas of the image created by light scattered at the surface. Dopes for this purpose were popular before the advent of the many modern "lustre" surfaces, combining a grained or textured base with a fine surface gloss. It is doubtful if such surfaces are improved by treating with encaustic paste, megilp and similar preparations.

ENDOSCOPIC PHOTOGRAPHY. Technique of photography inside normally inaccessible cavities, using specially designed optical instruments and camera attachments.

Endoscopes. An endoscope (Endo-scope: from Greek, within + to examine) is an instrument, usually tubular, which can be passed into a narrow orifice for the purpose of examining internal structure. Until recently the connotation was exclusively medical, but endoscopic examination now forms part of industrial practice also.

In its simplest form an endoscope consists of a rigid tube open at both ends. This can be made to carry a miniature lighting system, either proximally to shine down the tube, or distally to illuminate the region beyond the tip. Although this is primarily an instrument for visual examination, provision can be made for the attachment of a motion picture, still, or television camera. Variations of this arrangement form the basis of the Brubaker (U.S.A.) photo-endoscopic equipment. The term speculum is reserved for a simple endoscope when its length does not exceed its bore diameter by more than five times.

The present trend, however, is to use an endoscopic telescope in conjunction with a sheath, an open-ended endoscope, or a speculum which is usually made also to carry the lighting system. Light is generally piped towards the distal end of the telescope through a separate quartz rod. The Vulmirèe system (France), which was developed first, uses an incandescent light source for visual examination and cine photography, whereas the Storz equipment (Germany) favours electronic flash and is designed for still photography. The advantages of this basic optical arrangement are a wide angle of view, great

TYPES OF ENDOSCOPE. Top: *Direct endoscope.* Upper centre: *Forward system.* Lower centre: *Right-angle system.* Bottom: *Retrograde endoscope. The figures indicate the angle in degrees between the axis of the instrument and the viewing direction.*

MAIN VIEWING AND ILLUMINATING SYSTEMS: A, proximal illumination used mainly in conjunction with wide-bore instrument or specula. B, Distal illumination provided by miniature filament lamp on a separate stalk. C, Quartz rod piped light system. The telescope and rod are embraced by another tube not shown. The light beams are shown shaded in each case.

tolerance in terms of depth of field, and the utilization of smaller and lighter cameras.

By definition, endoscopic telescopes are long in relation to their diameter. They range from 10 cm. in length by 2.8 mm. in diameter to 40 cm. in length by 6 mm. in diameter. They consist of a varying number of optical repeater systems to relay an image from the tip to an eyepiece—to which a camera may be attached—with the minimum loss of light. The terminal angle of view may be deflected by prisms.

Application. The laryngoscope, bronchoscope, oesophagoscope, gastroscope, cystoscope, proctoscope and sigmoidoscope are examples of instruments which can be passed into the natural orifices of the body, whereas the thoracoscope, peritoneoscope and culdoscope require a surgical incision in the chest, abdominal wall, or vaginal vault for their respective introduction. The auriscope is the shortest of the open-ended speculum type of instrument and the ophthalmoscope and retinal camera are endoscopes of a different order, there being no direct connection between the instrument and the body of the subject.

TYPICAL MEDICAL ENDOSCOPES. A, auriscopes or otoscopes. Speculum type with battery in handle. B, cystoscope with distal illumination and telescope optics. This is shown on the same scale as A.

Instruments such as the bronchoscope and sigmoidoscope consist essentially of a rigid tube of appropriate bore, carrying an obturator to facilitate introduction; small lamps are carried at the distal or proximal end to illuminate the orifice. Telescope optics are optional. More complex instruments such as the gastroscope and cystoscope invariably embody miniature telescopic optical systems so that a magnified or angled view can be obtained. The gastroscope is very often partly flexible at its tip.

Many of these instruments are immediately adaptable for industrial use. For example it is possible to examine car cylinders through the spark plug opening without removing the cylinder head; the inspection of pipes and drains for internal corrosion, scaling etc. can be carried out through inspection ports and this applies also to the testing of boilers. Sometimes, however, a more rugged construction is required and waterproof or other protective housings are a possibility.

In medical applications the endoscope is usually under the control of the surgeon because dexterity in the manipulation of the instrument is of the greatest importance. In such circumstances it may prove necessary to attach or remove a recording camera quickly. Such attachment should not be too permanent lest the safety of the patient or the convenience of the surgeon be in jeopardy. To this end a loose three-pin bayonet, or a cone or cup seating, whereby the camera can readily be applied to the telescope or endoscope with the fingers forms the general method; magnetic seatings have also been advocated. If any camera is attached to an endoscope it must be possible to view the field up to the moment of or during exposure; some form of reflex viewing is therefore necessary for both still and cine photography. It may also be necessary to provide a counterbalanced suspension for the entire equipment. Lighting must be cool and the operating voltage must be low or completely isolated to minimize the risk of electric shock. In industry these problems are simplified by the absence of such rigid requirements.

Fibre Optics. The quality of image resolution by fibre optics is probably not yet high enough to compete with conventional systems, but may be of some use in difficult situations; the definition obtainable is more on a level with television criteria. From a theoretical standpoint the application of fibre optics is confined to: (1) the design of flexible endoscopes, (2) guiding

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

illumination along a tortuous path at the expense of considerable light loss, and (3) the connection of telescopes to heavy or bulky recording equipment.

It seems likely that developments along these lines will lend improvements to present techniques which were based initially on the concepts of Brubaker but are now being largely replaced by the more compact Vulmière system.

ENERGIATYPE. A paper process invented by Robert Hunt in 1844; later called Ferrotype because protosulphate of iron was used as developer. It is not to be confused with the later kind of ferrotype or tintype.

ENGLAND, WILLIAM, ?–1896. English daguerreotype portraitist in London in the mid-1840s, later known for his views of Switzerland, the Tyrol and Italy. Took thousands of stereoscopic views for the London Stereoscopic Company 1854–63 in Ireland, America, France, Switzerland and at the International Exhibition in London, 1862. Invented the focal plane shutter with variable slit 1861.

ENLARGED NEGATIVE. A number of special printing processes are too slow for anything but contact printing. If large prints are to be made from small negatives by any of these processes, they cannot be made by enlarging direct on to the sensitive material. An enlarged negative must be made, and from it contact prints made on to the particular type of printing material.

Contact printing may also be the faster method for making large numbers of prints from one negative. For very large production runs it may even become necessary to print simultaneously from several duplicate negatives.

Enlarged negatives can be made either via a positive transparency or by direct reversal.

Positive Transparency Method. Here a diapositive is made by contact printing the negative in the normal way. The positive is then projected in the negative carrier of the enlarger on to a slow non-colour-sensitive film or plate which is then processed to give the enlarged negative. This method allows considerable adjustment to be made in the contrast and density of the duplicate, while part only of the image may be enlarged if the rest is not required.

If a same-size duplicate negative is required, it is simply printed by contact from the transparency. Enlarged or duplicate paper negatives may also be made in this way.

Direct Reversal Method. Enlarged negatives can alternatively be made by projecting the negative on to an ordinary plate or film and processing the enlargement to give a reversed image. At the same time it is generally more satisfactory to use materials specially designed for reversal processing.

The original negative must be inserted the wrong way round in the negative carrier of the enlarger so that the emulsion side faces away from the lens. If this is not done, the enlarged negative will have the image reversed left to right, and be unsuitable for contact printing.

The image on duplicate negatives made by direct reversal and by contact will be the wrong way round in any case, unless the negative is turned over for printing, and in the case of contact printing the image will lose some sharpness because the emulsion surfaces of negative and duplicating material are not in direct contact.

See also: *Duplicate negatives.*

ENLARGER

In the early days of photography, photographic prints were mostly made by exposing a piece of sensitized paper in contact with the negative. This produced a positive image the same size as the negative image—satisfactory at a time when negatives were big. Nowadays, with the popularity of small negative sizes, big prints are made by optical projection printing.

The apparatus in which the printing process is carried out is called an enlarger. This projects an image of the negative on to the sensitized paper so that, by adjusting the distance between lens and paper, it is possible to obtain almost any degree of enlargement.

There are two principal kinds of enlarger: vertical and horizontal. The vertical type is used almost exclusively in everyday photography; the horizontal type was popular in the early days but is too cumbersome for normal printing; it is now used only in certain specialized branches of photography. There is a third, fixed focus, type of enlarging device which has an extremely limited scope and is practically obsolete.

All enlargers employ the same working principle. The negative is brightly lighted and its image is focused by a lens on to a sheet of sensitized paper. After a sufficient time of exposure, the paper is processed to give an enlarged positive image. The different degrees of enlargement are obtained by adjusting the distance between the lens and the negative and the lens and the paper. As with a camera, the two are inter-related (the lens-to-paper distance corresponds to the image distance in the camera, and the lens-to-negative distance to the object distance) for a given focal length of lens.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

VERTICAL ENLARGER. The optical system of the conventional vertical enlarger consists of a lamp (usually opal or sprayed) and a condenser which spreads the illumination evenly over the negative in the negative carrier. The negative is projected on the baseboard by the lens. Raising or lowering this entire unit alters degree of enlargement; movement of lens controls sharpness.

To obtain a high degree of enlargement involves raising the enlarger so that the lens is a long distance above the baseboard; for a smaller degree of enlargement, the lens is brought nearer to the paper surface (and at the same time farther away from the negative). For enlarged printing the lense-to-paper distance is always bigger than the lens-to-negative distance. The scale of enlargement follows the normal rules for optical magnification: $M = v/u$. (v = lens-paper distance; u = lens-negative distance.)

All enlargers have certain basic parts in common—i.e., a means of illuminating the negative, a holder for the negative, a lens (usually with provision for focusing) and a paper holder. The first three items are usually assembled in a single unit which is moved bodily towards or away from the paper holder or easel to change the scale of enlargement. The lens is focused either independently or automatically to produce a sharp image on the easel.

ILLUMINATING THE NEGATIVE

The problem common to all types of enlarger is that of illuminating the negative brightly but evenly. If the illumination is weak, it is difficult to focus the enlarged image visually, and the exposure becomes unduly long; if it is uneven, the paper will be exposed unevenly and give a patchy print with some parts over- and some under-exposed. There are various ways of achieving correct results.

The negative image is made up of varying densities of silver deposit distributed in a layer of virtually transparent gelatin. When rays of light fall on it, some are blocked by the silver deposit, and some pass straight through the clear parts of the negative. If the light rays reach the negative in the form of a directed beam, the rays passing through remain mostly inside a fairly narrow cone; if the original rays are diffused, they will strike the negative from all angles and will fan out in all directions equally when they emerge from the other side. In this case there will be no bright central cone of rays.

When an illuminated negative is being projected in the enlarger, the only useful rays emitted by the light source are those that fall on the enlarger lens. Any rays of light that do not strike the lens are useless. Rays that are already directed towards the lens before they reach the negative will generally fall somewhere on the lens and pass through to form an image. Even though the rays will mostly emerge in a cone and not in a parallel beam, the greater part of the cone will fall inside the area of the lens.

If the rays are not pointing in the direction of the lens when they fall on the negative, the cone of light leaving the negative will either miss the lens altogether, or only the outer fringe will fall on it. So, viewed from the point of view of the lens, the image patch illuminated by the ray will either appear dark or at least very much less bright than if the ray had originally been pointing towards the lens. But if all the rays used for illuminating the negative are directed towards the lens, then, when viewed from the lens, the negative will appear uniformly brightly illuminated.

Direct Illumination. So one effective way of illuminating the negative is to ensure that all rays of light from the source converge in a cone with its apex at the lens. All the rays from the source that pass through the negative will then fall on the lens and help to form an image on the easel. This condition is achieved by placing a suitably shaped reflector behind the light source, and a condenser, composed of one or more lenses, between the source and the negative. The reflector redirects all the rays travelling away from the negative back to the source. The condenser collects the direct light rays from the source and the indirect rays from the reflector and concentrates them into a cone of light. With a perfect reflector and condenser system and a point source of light, the tip of the light cone lies inside the disc of the lens and no light is wasted.

In practice the cone of transmitted light is never focused exactly on the back of the lens because such an arrangement would call for

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

re-focusing for every change in the scale of enlargement with its consequent alteration of the negative/lens separation. The light is made to converge on a point beyond the lens so that the section of the cone of light at the plane of the lens is somewhat wider than the disc on the lens. This wastes some of the light but it allows the lens to be focused over a wide range of scales of enlargement without any need to re-focus the illumination.

Diffused Illumination. On the other hand, if the rays from the light source are completely diffused in all directions, then the rays that pass through the negative will emerge in all directions and not in a concentrated cone. Every illuminated image patch will radiate light uniformly in all directions like a tiny point source. Some of this light will fall on the lens and pass through to form an image. And whether the image patch is at the centre of the negative or at the edge, the total amount of light it radiates will be the same, and the proportion that falls on the lens will be the same. So, once again, when looked at from the lens, the negative will appear uniformly illuminated.

This type of illumination can be achieved by placing a diffuser between the light source and the negative and employing a reflector with a matt diffusing surface behind the source. But whereas in a perfect condenser system all the light from the source is usefully employed, in this second system only a proportion of the total light leaving the source falls on the lens and helps to form an image. In practice this may be only a few per cent of the light passing through the negative; hence it is very much less efficient to illuminate the negative by diffused light than by direct light.

Callier Effect. There is one more important difference between direct and diffused negative illumination. When direct light falls on the negative image it passes straight through the clear parts, but where the rays strike even a thin density they are broken up and scattered by the silver grains so that they emerge in all directions as though they had been diffused by a sheet of opal or ground glass. This means that the highlight areas of the print—i.e., under the denser parts of the negative—receive less light than they should, so they appear whiter. In other words direct illumination increases the contrast of the negative, leading to more contrasty prints.

This selective scattering of the light by the denser parts of the negative is known as the Callier effect after its discoverer. No such effect takes place with diffused illumination of the negative since the rays falling on the clear areas of the negative are already diffused.

A scratch or other physical blemish on the

ENLARGER ILLUMINATION SYSTEMS. Left: Direct light from an opal lamp, with an opal diffusing screen. Yields soft diffused light and subdues fine image detail, especially blemishes. This is also the cheapest lighting system to produce for an enlarger, and is therefore found in a number of inexpensive models. Centre left: Indirect diffused light from two opal lamps with an opal diffuser. The usual system for enlargers for large negatives. Some modern enlargers replace the bulbs by a grid-shaped fluorescent tube. Centre right: Direct light from clear lamp and condenser. Yields intense light, increased image contrast, and shows up finest detail. However, needs constant refocusing of lamp. Right: Direct light with opal lamp and condenser. The most common system in use, with most of the advantages but not the drawbacks of the clear lamp and condenser.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

negative scatters the light just as the silver grains do, and direct illumination produces a similar exaggeration of the contrast. So scratches and blemishes and grain—all tend to be rendered more obvious in the print by direct than by diffused illumination. For the same reason, since the resolution of detail depends on the contrast between adjacent light and dark areas, direct illumination, which exaggerates tone contrast, automatically gives better resolution of detail than diffused illumination.

The Callier effect is greatly reduced with negatives not containing silver grains, such as the dye images of colour films. This is because the dyes are transparent, and not opaque particles like silver.

Lighting Systems Compared. To sum up the differences: direct illumination makes more efficient use of the light available; it increases contrast and gives better resolution. But it makes grain, scratches and blemishes more obvious. Diffused illumination gives softer contrast (which is sometimes an advantage) and lessens the effect of grain, scratches and blemishes. But it is relatively less efficient and calls for either a much more powerful light source or longer exposures than direct lighting.

In practice an enlarger may have either direct, diffused, or semi-diffused illumination.

Direct illumination is produced by using a point-light source in conjunction with a polished spherical reflector and a condenser, consisting generally of two plano-convex lenses assembled with their flat faces out. This system focuses both direct and reflected images of the filament in the enlarger lens. It is mostly used in enlargers that are run off a portable battery in situations where no main electricity supply is available. Such enlargers are fitted with a motor-car headlamp type of bulb and the high efficiency of the illumination system makes up for the relatively low power of the light (24 or 36 watts).

Diffuse illumination may be produced: by mounting a large diameter opal bulb in a matt white reflector with one or more sheets of opal or frosted glass between the light source and the negative; by using an evenly distributed source of light behind the negative; or by illuminating the negative entirely by light reflected from lamps screened so that no direct rays can fall on the negative.

Enlargers of this type are manufactured for both very small and very large negatives but they vary widely in their construction because of the great differences in the types of light source.

Enlargers for very big negatives rarely use any other kind of illumination than diffused. This is partly because big condensers are expensive (and more difficult to make) and partly because the heat from the enlarger lamp may crack even thick condenser lenses.

Semi-Diffused Illumination. In this type of illumination, the direct light of a condenser arrangement is partially diffused so that its optical adjustment is no longer critical. The light is therefore made appreciably larger than a point source (generally an opal bulb) with a white reflector, rather than a polished one. The greater part of the light is still directed in a broad, slightly convergent beam on to and around the back of the lens, but the diffusion is sufficient to smooth out the effect of incorrect focusing of the light source and condenser. It also prevents an out-of-focus image of the light source itself—e.g., the filament of a tungsten lamp—from being superimposed on the image of the negative on the easel.

Semi-diffused illumination is the most popular type for normal enlarging because it combines most of the advantages of both direct and diffused systems while the characteristic disadvantages of each tend to cancel out.

Light Sources. The light source in an enlarger may be one of the following types: tungsten filament (lamps), high pressure mercury arc, vapour discharge tubes, non-electric sources of various types.

Tungsten filament lamps with fully diffusing opal or frosted glass bulbs are the commonest form of light source for semi-diffused illuminating systems. They provide a bright sphere of practically uniform illumination. Consumption ranges from 60 to 150 watts according to the enlarger but for specially intense lighting—e.g., for very dense negatives, or unusually big enlargements—an over-run or Photoflood type may be substituted. (As a rule the ordinary domestic pearl or opal bulb is not suitable because it usually has the maker's name printed on the end of the bulb and this is almost certain to produce a blurred image on the printing paper.)

A number of such bulbs are used in diffused-light enlargers to illuminate large negative areas evenly. Various lamp arrangements are employed, and in some cases the lamps are arranged movably so that they sweep all over the negative area to provide specially even illumination. Since a number of powerful tungsten lamps generate a great deal of heat, enlargers of this kind (usually industrial or professional models) may incorporate blower cooling. There, an airstream from a fan is blown through the enlarger lamp house to cool the lamps, and especially the negative.

Lamps of the car headlamp type may be fitted in enlargers intended to be used away from main supplies of electricity. These are either 6 or 12 volt with a consumption of 24 or 36 watts. In order to make the most of the small amount of light available the lighting system with such lamps is of the undiffused direct light type and the condenser must be re-focused for each change in the scale of enlargement.

The normal type of projection lamp bulb is also used as the light source in a number of enlargers—mostly for miniature negatives. In

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

this type of lamp the filaments are accurately positioned and closely clustered while their rigid mounting prevents them from moving out of the focal plane of the condenser and reflector system. Projection lamps have a tubular instead of a pear-shaped envelope so that they can be mounted close to the condenser and reflector. This arrangement makes the maximum use of the available light.

Because of the filament arrangement these lamps must be mounted vertically, so if they are used in a vertical enlarger the lamphouse must be specially designed and include a mirror to direct the light downwards.

High pressure mercury arc lamps utilize an arc struck between tungsten electrodes in a small glass or quartz tube containing mercury vapour with a trace of argon. The tube is enclosed in a partly evacuated outer glass envelope to limit the heat loss and maintain the pressure at the arc. Such lamps have a very high luminous efficiency and are excellent for making very big enlargements—e.g., photo-murals—where an extremely brilliant light source is necessary to keep exposures within reasonable limits. A disadvantage is that once the lamp is switched off the arc cannot be struck again until it has been allowed to cool off for several minutes. In common with all arc lamps high pressure mercury vapour lamps must be operated through a current-limiting choke. They have a life of about 1,500 hours.

Mercury vapour, fluorescent and cold cathode tubes are used principally for large negative sizes that cannot be evenly illuminated by any of the more compact light sources. A number of tubes are arranged side by side, or a single long tube is bent to form a grid so that the whole of the negative area is covered. The result is an even light which requires little further diffusion. Cold cathode tubes in particular are excellent light sources used in this way. Their light is practically cold, so the lamp house can be reduced to a mere shallow box; they can be used intermittently with no delay after switching on, and the light is highly actinic. An 80 or 100 watt lamp is ample for most purposes and the useful life may be 6,000 hours or more.

Where no electricity supply or battery power is available, practically any of the traditional non-electric sources may be used—e.g., coal gas, acetylene and other gas burners, and paraffin wick and mantle type lamps. Such sources are generally more suitable for burning vertically to allow for a ventilating chimney immediately over them. For this reason they are almost always used only in horizontal enlargers.

CONSTRUCTION

An enlarger is made up of two principal units, the head assembly and the easel. The negative is held in a carrier in the head assembly and projected on to a sheet of sensitized paper on the easel. The two units are mounted on a track consisting of a rigid tube or a pair of guide rails so that the distance between them can be adjusted to vary the enlargement scale.

The whole arrangement may be designed to work with the guide rails horizontal or vertical. In the vertical arrangement, the track forms the support for the head assembly and is rigidly mounted on the easel to form a base; in the horizontal arrangement the two units merely rest on the track.

The head assembly consists of the lamphouse, the negative carrier, the lens with its focusing mechanism.

Lamphouse. The lamphouse is a ventilated metal box which houses the light source, a shaped reflector and a condenser unit or diffusing screen or both. The reflector is usually spherical and the light source is placed at its centre of curvature so that all rays falling on the surface are reflected back through the source. In a direct illumination system the reflector is polished, but for diffused and semi-diffused systems it is painted matt white or satin finished.

Most enlargers of the direct or semi-diffused type have condensers with a focal length approximately half that of the enlarger lens. As the condenser must be big enough to cover the whole negative this requirement produces an abnormally thick lens in the larger formats if a single lens is used. In practice, single condenser lenses are used only for 35 mm. and other small negatives. It is customary to use a plano-convex lens with the flat face towards the negative. (It may even be pressed into contact with the negative to keep it flat.)

For negative formats with a bigger diagonal than about 2 ins. two plano convex lenses are employed with their flat faces outwards. These are equivalent to a single lens of twice the thickness, but it is easier to make two separate plano-convex lenses than one double convex. The double assembly suffers less from aberrations, and it is less likely to crack under the heat of the light source.

In direct and semi-diffused lighting systems, the position of the lamp is usually adjustable with respect to the condenser so that the light can be roughly focused to concentrate the greater part of the rays on the back of the enlarger lens.

The typical vertical enlarger lamphouse is constructed in the form of a cylinder with a hemispherical cap which forms or houses the reflector. The lamp is mounted on the end of a metal tube which enters the top of the cap through a friction-tight bush. This enables the lamp to be moved up or down to focus the beam. In practice the lamp is moved about with no negative in the carrier until the baseboard is evenly illuminated.

A vertical enlarger lamphouse designed to work with a projection type lamp has a hori-

zontal lamp chamber in which the lamp is mounted vertically in front of a reflector which projects the light on to a 45° mirror. From the mirror the light is reflected down on to the condenser. This arrangement is necessary because projector type bulbs must be worked in a vertical position, and it also makes for more efficient cooling.

On a horizontal enlarger the lamphouse is a rectangular box with a ventilating chimney on top. One end of the box is taken up by the condenser, and the lamp and reflector are mounted on a movable slide in front of it so that the light can be focused to give uniform illumination. This type of lamphouse is convenient for non-electric light sources such as gas or oil burners.

The simple types of diffused light lamphouse are similar in construction to the normal condenser type. The condenser unit is replaced by one or more sheets of opal glass and the reflector is given a matt finish instead of being polished. As the light is almost always an opal lamp and not a point source, the shape of the reflector generally departs from the conventional spherical section so as to give even illumination right to the edges. The lamp is mounted in a fixed holder; there is no need for it to be adjustable. This system is only suitable for small or medium sized negatives—e.g., 35 mm. up to 2¼ × 3¼ ins.

Another basic type of diffusing lamphouse has a number of lamps—or a single, shaped tubular lamp—arranged in a trough around the outside so that the light is directed on to a central dome-shaped reflector. Light from the reflector alone is allowed to fall on the negative, the direct rays from the lamps being cut off by the inside wall of the trough. Lamphouses of this type can be made to evenly illuminate negatives of anything up to quarter-plate size—i.e., 3¼ × 4¼ ins. (9 × 12 cm.).

Finally there is the flat, box-shaped lamphouse that houses a grid of tubular mercury vapour—or more recently, the popular cold cathode-discharge lamps. In this type the grid extends over the whole of the negative area and the tubes are practically touching. The result is an evenly distributed light right to the edges of the negative even without the addition of a diffuser. Since the light given out by this type of lamp is practically cold, ventilation is no problem and the lamphouse is little more than a flat box just big enough to hold the grid. The necessary control gear may be built in to the lamphouse or it may be supplied as a separate unit.

Lamphouses of this type are suitable for negatives of all sizes, but particularly for the larger formats.

Negative Carrier. The function of the negative carrier is to hold the negative flat and parallel to the lens plane at the right distance from the lens.

The carrier usually fits into a slot in the enlarger body and supports the negative in front of the condenser. With some carriers it is possible to rotate the negative by turning a knob on the end. This enables the operator to square up the image with the sides of the paper easel. The movement is particularly valuable on horizontal enlargers where it is not always easy to adjust the paper position.

Plates to be enlarged are held in a frame type carrier in which the plate lies in a shallow rebate around the inside of the frame and is retained by spring clips. Or it may be held in a double frame, hinged to open like a book.

Films may be sandwiched between sheets of glass in a frame, or they may be held by the edges only in a glassless carrier. The glass sandwich type of holder is used for film negatives of all sizes, but the glassless type is suitable only for miniature or small negatives. Glassless carriers have the advantage of offering only two film surfaces for dust to cling to, whereas in the sandwich type there are four glass surfaces in addition. But any film larger than 2¼ × 2¼ ins. is apt to buckle under the heat of the lamp and go out of focus—and even miniature negatives may give trouble if the ventilation is inadequate or the lamp is left switched on too long.

Film negative holders normally incorporate a mask, or one half of the frame is shaped to

CC-0. Jangamwadi Math Collection. Digitized by eGangotri

serve the same purpose. The opening in the mask is the exact size of a single frame without allowance for the clear margin. This ensures that no unnecessary light passes through the negative to form a possible source of stray reflections that might fog the enlarged image.

In some enlargers the negative stage has built-in adjustable masks which permit masking down of the image area as required.

In certain miniature enlargers the negative is simply held against the lower face of the condenser or diffuser by a metal plate cut away to mask the negative area. This arrangement helps to keep the negative flat but may defeat its own object unless the glass surface is well cooled by efficient ventilation.

Roll film is often handled in the complete roll, and 35 mm. film either in the roll or in strips of six or nine frames. So the negative holder, while keeping the film under pressure for enlarging, must permit it to be moved on to a new frame without being removed from the enlarger. In the cheapest instruments the two halves of the carrier are simply held together by a spring with just enough pressure to allow the film to be drawn between them. With this arrangement there is always the risk of scratching from particles of grit or rough spots on the face of the carrier in contact with the film. Better enlargers have a lever which releases the pressure while the film is being moved.

NEGATIVE CARRIERS. 1. Open frame carrier for plates. 2. Double glass sandwich for films; keeps the negative flat, but collects dust on four surfaces. 3. Single glass plate and metal frame. 4. Condenser and metal frame; often used in 35 mm. enlargers. 5. Glassless with heat-absorbing glass; limited to small negative sizes as larger films distort.

In most enlargers the negative carrier is inserted through a light-trapped opening and is held rigidly in the beam of the light in the focal plane of the lens. Some of the more expensive instruments, however, have a pivoted housing for the carrier which enables the negative to be tilted at an angle in conjunction with an opposite tilt of the easel to correct for converging verticals. This device gives a more accurate correction than a simple tilt of the easel (which corrects the convergence but elongates the subject unnaturally and puts part of the image out of focus).

Lens. The lens is connected to the negative carrier housing by a bellows or a telescopic metal sleeve so that it can be moved to and fro for focusing the image.

The focal length of the lens depends upon the format of the negative to be covered. Generally the focal length is equal to or somewhat longer than the diameter of the condenser and also about equal to the diagonal measurement of the negative in question—i.e. equal to the focal length of the normal camera lens for that size.

The maximum aperture of the lens must give sufficient illumination on the paper to focus by when an average negative is being enlarged to the fullest extent possible.

While interchangeable lenses of certain cameras (mainly miniatures) can be used for enlarging, the use of a high-quality enlarging lens is preferable for two reasons. One is that camera lenses are usually corrected to give best definition at high reduction—with the lens focused on distant subjects and with a comparatively short lens-to-image distance. In enlarging it is the object distance (negative to lens) which is small and the image distance comparatively greater. The second reason is that high-speed camera lenses may contain several cemented elements which can get damaged by the heat from the enlarger light. This is liable to occur with enlargers using a powerful directed light source.

The lens may be equipped with click-stop adjustment—i.e., the diaphragm is controlled by a lever which engages with a click that can be felt and heard at each stop value.

A red or orange glass filter may be fitted in front of the lens in such a way that it can be moved into the light beam to hold back the actinic rays. This allows the position of the sensitized paper to be adjusted with the enlarger switched on. The filter is normally hinged or pivoted in front of the lens. On some of the large professional models it slides behind the lens.

Nowadays practically all enlarger lenses are bloomed to cut down internal reflections and increase the image contrast.

Focusing Mechanism. The image is focused by moving the lens closer to, or farther away from, the negative. This calls for a light-tight sleeve between the lens and the negative and a mechanism for adjusting the separation.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

TYPICAL LENS AND CONDENSER SIZES

Negative Size ins.	Negative Size cm. (approx.)	Diagonal of negative or minimum diameter of condenser ins.	Diagonal of negative or minimum diameter of condenser cm.	Focal length of lens ins.	Focal length of lens cm.	Maximum aperture
¼ plate (3¼ × 4¼)	9 × 12	6	15	5–6½	13–15	4–5·6
2¼ × 3¼	6 × 9	4⅓	11	4–5	10–13	3·5–4·5
2¼ × 2¼	6 × 6	3½	8·5	3–4	7·5–10	3·5–4·5
1 × 1½	2·4 × 3·6	1¾	4·3	2–3	5–7·5	3·5

The minimum condenser diameter for an enlarger with a tilting negative carrier is always about 25 per cent larger than for a non-tilting type to ensure that the full negative area is always well within the light beam.

In the simplest arrangement the lens is coupled to the head assembly by a pair of metal tubes which telescope one into the other. A pin in the inner tube engages with a helical slot in the outer, so that turning the lens moves it in or out. In a more elaborate version of this system the pin and slot is replaced by a multi-start helical thread, and this may be further modified so that the lens does not rotate. These systems provide a limited extension for one particular focal length only.

In the more elaborate units, the lens panel is mounted on a rack and pinion slide or a set of rails and is connected to the enlarger head by a flexible opaque bellows. This arrangement permits any desired length of extension and can be designed to provide the necessary range of movement for lenses of several focal lengths. It is popular for enlargers intended for more than one size of negative—e.g., 35 mm. (2 ins. lens) and 2¼ × 2¼ or 2¼ × 3¼ ins. (3½ ins. lens). This method also allows for some degree of reduction.

The movement of the lens panel may be controlled by the rack-and-pinion mechanism mentioned above, or by a friction drive. Some models incorporate a micrometer screw for fine focusing. A locking screw may also be provided to set the focusing position.

The maximum scale of enlargement is obtained when the lens is racked back so that the negative lies very near its back focus; this results in an almost infinite scale of enlargement. As the lens is moved farther away from the negative the scale gets progressively smaller until the separation is approximately equal to twice the back focus. At that point the negative is reproduced 1 : 1—i.e., the negative and projected images are the same size. Further extension gives a reduced image.

FOCUSING MECHANISM. Left: *Helical focusing mount; the unit carrying the lens screws in and out by a coarse thread.* Right: *Rack-and-pinion system with bellows.*

LENS-TO-BASEBOARD DISTANCES AT VARIOUS MAGNIFICATIONS

Magnification (Diameters)	Focal Length of Lens 2 ins. (5 cm.)	3 ins. (7·5 cm.)	4⅛ ins. (10·5 cm.)	5⅜ ins. (13·5 cm.)
1	3·9 in. (10 cm.)	5·9 in. (15 cm.)	8·3 in. (21 cm.)	10·6 in. (27 cm.)
2	5·9 in. (15 cm.)	8·9 in. (22·5 cm.)	12·4 in. (31·5 cm.)	15·9 in. (40 cm.)
3	7·9 in. (20 cm.)	11·8 in. (30 cm.)	16·5 in. (42 cm.)	21·2 in. (54 cm.)
4	9·9 in. (25 cm.)	14·8 in. (37·5 cm.)	20·7 in. (52·5 cm.)	26·6 in. (67·5 cm.)
5	11·8 in. (30 cm.)	17·7 in. (45 cm.)	24·8 in. (63 cm.)	31·9 in. (81 cm.)
6	13·8 in. (35 cm.)	20·7 in. (52.5 cm.)	29 in. (74 cm.)	37·2 in. (95 cm.)
8	17·7 in. (45 cm.)	26·6 in. (67·5 cm.)	37·2 in. (95 cm.)	49·9 in. (127 cm.)
10	21·6 in. (55 cm.)	32·4 in. (82·5 cm.)	45·5 in. (116 cm.)	58·5 in. (148 cm.)
12	25·6 in. (65 cm.)	38·4 in. (97·5 cm.)	53·7 in. (136 cm.)	69 in. (175 cm.)
15	31·5 in. (80 cm.)	47·2 in. (120 cm.)	66·1 in. (168 cm.)	85 in. (216 cm.)

These distances are slightly rounded off.

The focusing range is normally designed to give a range of enlargement from infinity to same size with a particular lens. If more than one lens is catered for, the focusing range must start with a lens negative separation equal to the back focus of the shortest focus lens and extend to at least twice the focal length of the longest focus lens—i.e., in an enlarger designed for both 35 mm. and 2¼ × 3¼ ins. negatives it must extend from 2 ins. (5 cm.) to at least 7 ins. (18 cm.). If such extreme reductions are needed that the lens to negative separation with the normal lens would need to be greater than can be achieved, then a shorter focal length lens should be used instead.

Automatic Focusing. The lens panel may be racked along the slide by a hand-operated knob or lever, or it may be coupled to the head raising and lowering mechanism so that it auto-

matically moves the panel to give the correct extension for any degree of enlargement—i.e., according to the distance of the enlarger head from the easel. This is done by moving the lens panel by a rocker arm riding on a suitably shaped cam or profile plate attached to the fixed part of the enlarger.

Rangefinder Focusing. The enlarging head may also incorporate a ranging device. This is usually some form of split-image system in which two separate images—either of the negative, or of an illuminated slit—are projected on to the baseboard and are brought into coincidence by moving the lens focusing control. When the images coincide, the negative will be sharply focused. It is easier to focus this way than by trying to decide when the image is at its sharpest.

The method most generally used is to insert a mask behind the lens so that each half of the lens forms its own image of an illuminated slit mounted in the focal plane. When the two halves of the slit are brought into register the lens is sharply focused. The slit image is then moved out of the way and the negative carrier slid into position, bringing the negative into the focal plane previously occupied by the slit.

Magnifier Focusing. Any of the normal types of focusing magnifier may be used for determining when the image is sharp. The basic principle with all such systems is to reflect part of the enlarged image on to a viewing screen with a magnifying lens above it. When the magnified screen image appears sharp, the image on the easel will also be sharp. Magnifiers of this type are not usually supplied with the enlarger; they are bought as an accessory.

Magnifiers of this type must be very accurately made really to be an advantage; a slight difference in the distance between the mirror and screen and mirror and baseboard will result in inaccurate focusing on the final print.

Instrument Focusing. The sharpness of the image on the baseboard can also be checked with a photo-electric sharpness meter. This compares the contrast of the sharp image with the contrast when it is unsharp. A special high-contrast target (such as a black-and-white screen pattern) is used in the negative carrier during focusing. The image is projected on a special photocell system, and the sharpest position found by observing the point where the reading of a measuring instrument is at its highest.

Raising and Lowering Gear. The scale of enlargement is adjusted by altering the distance between the enlarger head and the easel. In the commonest vertical arrangement upright metal tubular columns or girders, anchored to the easel, support the head and form a track on which it can be slid up or down. It can be locked in any position by a clamp, and its weight may be counterbalanced by a cable passing over a pulley and attached to a suitable lead counterweight suspended inside the column.

The use of a weight and pulley is the most

FOCUSING AIDS. Left: *An opaque strip across the centre of the lens separates an unsharp image into two distinct images.* Right: *Rangefinder system using a split field; when the split line fuses on the baseboard, the image is sharp.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

simple system of providing a counterbalance, but enlargers also employ systems using springs instead.

The head may be raised by a rack and pinion mechanism or a friction wheel drive. Another method is to move it up and down by a head screw and nut in the same way as the tool rest of a lathe is moved along the bed.

On big enlargers the raising and lowering adjustment of the head is controlled by hand wheels at the front of the baseboard. On some advanced models the movement may even be motor driven.

In some enlargers the head is attached to the column by two sets of parallel links pivoted at each end so as to allow the head to move up and down while its axis remains vertical (this is commonly called a parallelogram movement). The weight of the head is counter-balanced so that very little effort is needed to raise it. A clamping screw holds the head firmly once it has been set at the desired height. This arrangement usually incorporates an automatic focusing mechanism coupled to the link motion in such a way that the image on the easel remains sharp over the whole range of movement of the head.

The head of the enlarger can usually be swung to the other side of the column so that the image can be projected over the edge of the bench to give extra big enlargements. On some enlargers the head can be turned through a right angle so that it projects the image horizontally. This turns the enlarger into a horizontal type with a maximum scale of enlargement limited only by the length of the printing room.

Commercial enlargers that have to handle both large and small negatives with a wide range of magnifications often have the head mounted on vertical rails fastened to the wall, or on twin tubular columns extending from floor to ceiling. This arrangement gives the necessary rigid support to the larger type of head required for such work. In such enlargers both the head and the easel can be moved up or down on the guide rails by handles coupled through bevel gears to associated vertical lead screws.

A similar mechanism is used on the larger horizontal enlargers for adjusting the relative positions of the body and the easel.

Easel. The easel supports the printing paper and must therefore be flat, rigidly held in relation to the enlarging head, and at right angles to the axis of projection.

There is a basic difference between the easel of a vertical and a horizontal enlarger. The easel of a vertical enlarger is horizontal, so there is no difficulty in arranging the paper on it in any required position with respect to the projected image. Once in position, the paper can be held down by a sheet of glass, or by pins at each corner or by a masking frame. So in this case the easel is simply a flat board or sheet of metal which also forms the support for the column. Some manufacturers give the board a white finish so that the whole image can be focused on it, others prefer a black finish to cut down the light reflected by the unwanted parts of the image and thus reduce the risk of fogging the paper. When the surface of the board is black, and this is by far the most advisable, the image must be focused on a piece of white paper of the same size as the proposed enlargement.

Paper holders for vertical enlargers have a white finish and an adjustable masking frame which can be set to the paper size. The image is first adjusted and focused on the masked area of the empty holder; the paper is then inserted and the exposure made. Sometimes the easel is covered with a layer of cork so that the paper can be held in place with pins. Another method is to coat the surface with a suitable, permanently tacky adhesive which holds the paper in place but allows it to be stripped off after exposure.

The easel of a horizontal enlarger is a more elaborate affair because it must incorporate the paper holder and allow the position to be adjusted. The usual horizontal enlarger easel consists of a stand holding a glass-fronted frame which is pivoted so that it can be either horizontal or vertical. The glass front is hinged to allow the paper to be inserted. The frame is fixed by a bolt in a vertical slot in the

stand; when the bolt is slackened off, the frame can be raised, lowered or turned to bring the image into the required position. The front of the easel is white with black lines marking out the boundaries of the various sizes of printing paper.

To use an easel of this kind, it is first placed at the right distance to give a sharp image of the required size. The frame locking-bolt is slackened off and the frame moved about until the image occupies the rectangle corresponding to the paper size. The frame is locked, swung horizontal and the glass front opened. A piece of paper is laid in position and the frame is closed and returned to the vertical for the exposure.

It may be locked at any intermediate angle for correcting converging verticals.

This type of easel may also be faced with cork or adhesive instead of glass to allow the paper to be pinned or stuck in position.

An adhesive support for the paper during enlarging can be made by pouring a layer of jelly into a shallow tray of suitable size. The ready-made composition used in "jellygraph" duplicators is excellent for the purpose, or a home-made substitute can be prepared as follows:

Soften 1 ounce (25 grams) of leaf gelatin by soaking in water for 24 hours. Drain off the water, pour over 6 ounces (150 c.cm.) of glycerine and heat in a double saucepan until the gelatin dissolves. A few drops of oil of cloves is added to prevent the mixture from deteriorating. The warm gelatin is poured into the tray and left to set. When cold the surface will be tacky enough to hold single weight paper firmly in position but it is not so successful with double weight papers.

After a time the surface may lose its tackiness by being covered by a film of grease or dust, but it can be restored by simply melting the mixture and allowing it to set again. This type of paper holder is particularly useful with horizontal enlargers where the paper must be held on a vertical surface.

Horizontal Enlarger. In principle there is no difference between a vertical and a horizontal enlarger. The horizontal arrangement was the first to be used, being simply an adaptation of the existing "magic lantern" type of slide projector.

Horizontal enlargers are not nowadays manufactured for the smaller and more popular negative size because the layout takes up much more space than the vertical arrangement, the paper is more difficult to control, and the image is not so easy to examine. The only remaining horizontal enlargers are those specially made for the larger plate formats—e.g., in photomechanical work, document copying and commercial and professional studios—where the weight of the assembly makes the vertical construction unnecessarily expensive.

Even so, because of the greater convenience in use and saving of space, the vertical arrangement is often preferred, notwithstanding the extra cost, even for the largest instruments.

The lamphouse of the typical horizontal enlarger is simply an oblong box housing a reflector, light source and condenser. A light-trapped chimney on top of the box carries off the hot air.

This type of house incidentally allows a variety of non-electric light sources to be used. The negative carrier on a horizontal enlarger is often equipped with movements that allow the negative to be rotated to level up the horizon and fitted to correct converging verticals. The lens panel is connected to the body by a bellows and is moved forward or backward by a rack and pinion mechanism.

The whole assembly is attached to the end of a pair of wooden or metal rails which carry the easel and keep it at right angles to the projection axis. Adjustment of the scale of the image is carried out by sliding the easel along the guide rails.

Horizontal enlarger design has remained practically unchanged for the past fifty years. The demand for this type is not great enough to justify the cost of press tools or moulds so the few that are made are hand built on the old pattern.

Even when the horizontal type of arrangement is more convenient—e.g., for making photomurals or other giant size enlargements—most workers prefer to use the head of a vertical enlarger to project the image and, in fact, many vertical enlargers are designed to allow the head to be turned through 90° for this purpose.

Fixed Focus Enlarger. The fixed focus enlarger (now practically obsolete) is simply a vertical enlarger designed to gives a standard size of enlargement—e.g., post-card—from one particular size of negative. It is usually made of the cheapest materials and components and built down to a price. The object of this type of instrument was originally to overcome the reluctance of the ordinary non-technical snapshooter to buy a miniature camera. The nega-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

tives produced disappointingly tiny contact prints and this type of user was not prepared to go to either the trouble or expense of making enlargements. The fixed focus enlarger gave him pictures big enough for his purpose with no more trouble than contact prints.

The arrangement was simply a long conical light-tight box with an opal lamp and diffuser at the narrow end and a paper holder at the opposite end. There was a slot for the negative holder and the lens was mounted in the centre of a suitably placed light-tight partition inside the box.

Enlargers used for commercial mass printing from specific negative formats are frequently also fixed-focus types. They are however appreciably more complex in the provisions for holding the paper (often in continuous rolls) and for automatic exposure measurement and timing.

Daylight Enlarger. A special type of fixed-focus enlarger has no lamphouse, its place being taken by a sheet of opal diffusing glass. When pointed towards the daylight an enlarged image of the negative is projected on to a sheet of bromide —or even print-out-paper—in the opposite end of the box. The paper is inserted and removed in the darkroom.

Some larger models were even built into a darkened room with the negative receiving daylight through a hole in the wall. Enlargers of this type are not made today.

Enlarging Adaptors. Various forms of adaptor have been manufactured in the past for converting a plate camera into an enlarger. The usual design consists of a lamphouse, condenser and negative holder which is attached to the camera in place of the plate back. The focusing extension of the camera must be great enough to allow a range of movement up to a distance of twice the focal length of the lens from the negative.

The advent of the cold cathode grid light source for enlarging has made it possible to design a compact adaptor in which the lamphouse is reduced to a shallow square box housing the discharge tube.

Another type of adaptor, now obsolete, enabled a plate camera body to be fitted to an aperture in the window blind of the darkroom. A sloping white-painted board outside the window reflected the sky light through the aperture and illuminated the negative in a holder fitted in the back of the camera. This arrangement went out of use as soon as electric lamps became available, but it is still employed by workers remote from electricity supply services.

Like all daylight printing methods it suffered from the variable nature of the light and the fact that no work could be done during the hours of darkness.

Ultra-miniature Enlargers. When ultra-miniature cameras first appeared, existing enlargers for 35 mm. and larger negatives were unsuitable for the small negative formats from 8 × 11 to 12 × 17 mm. Generally such enlargers did not have provision for bringing the lens near enough to the negative to permit the use of lenses of a short enough focal length to yield reasonable degrees of enlargment. Special ultra-miniature enlargers were therefore produced which were usually scaled-down versions of larger models.

Adaptors also exist for using a normal-size enlarger for ultra-miniature negatives. Such adaptors consist of a lens and negative carrier attachment which screws into the lens panel of the enlarger in place of the normal lens. The light beam from the enlarger illuminates the negative in its own ultra-miniature carrier, with the enlarging lens being part of the adaptor to focus the negative image in turn on the baseboard.

The lens in this case has its own focusing adjustment. The negative carrier takes ultra-miniature negatives in strips, and can accommodate image sizes frequently down to the frame size of 8 mm. cine film.

Enlargers for Colour. For making enlargements from colour negatives on to positive colour papers (or from colour transparencies on to reversal papers) the enlarger must provide some control of the colour of the printing light to correct the colour rendering of the final print. In their simplest form, colour

SIMPLE COLOUR ENLARGING SYSTEMS: Top: Filter turret fitted in front of enlarger lens for three-exposure printing. The turret carries three tri-colour (red, green and blue) filters which can be brought into position as required. Bottom: Filter drawer for subtractive printing. Printing filters of various strengths fit into a drawer between the negative and the light source to modify the colour of the printing light.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

enlargers incorporate a pull-out drawer in the lamp house to permit the placing of appropriately-coloured cyan, magenta or yellow filter foils of varying densities between the lamp and the condenser. The filter foils are available in standard sizes (for example 12 × 12 cm.). The correction is achieved by combining two or more filter foils of one or two colours and similar or different densities. The actual filter combination required depends on the colour of the enlarging light, on the characteristics of the printing paper and the colour balance of the negative. This is determined in each case by preliminary tests, and the colour print is made by a single exposure by the appropriately-filtered light.

An alternative method of making colour prints is to expose the paper three times through a red, green and blue filter respectively. The relative exposures through the three filters determine the colour rendering—again settled by preliminary tests. The filters in this case are mounted in front of the lens, either in a filter slide or a filter turret. Most normal enlargers can be adapted for this method of printing.

Enlargers for colour printing must have a light source with a continuous spectrum and a consistent colour quality. Tungsten lamps are the most usual enlarger lighting for colour, and are generally run through a voltage control circuit to ensure a constant operating voltage (and hence constant colour temperature) for consistent results. Certain types of fluorescent lighting have, however, also been used for colour enlarging.

More advanced colour enlargers may provide semi-automatic or automatic systems of light control in a special lamp house which can be used—interchangeably with the normal lamphouse—on standard enlargers. Such enlargers may use either the three exposure or the single exposure printing system.

For three-exposure printing, the lamphouse incorporates a red, green and blue filter which are switched in front of the enlarger lamp in turn (there may even be three enlarger lamps, each with its own filter). The filters are controlled by electric circuits, which move them into position for pre-determined times according to controls set on the enlarger head or on a separate timer unit. The latter may in turn be controlled by various photo cell systems that measure the intensity and colour quality of the light coming through the enlarger lens.

Colour enlargers for single exposure printing may incorporate one or more light sources with graduated cyan, magenta and yellow filters in front of them. External controls vary the position of each filter in the light beam, thereby adjusting the amount of each colour component of the light. This filtered light is mixed in an integrating sphere or reflector arrangement to provide thoroughly diffused light of uniform colour. In semi-automatic and automatic units, the filtering selection is controlled from a photo-electric measuring system which measures the colour of the light coming through the enlarger lens.

PRINCIPLE OF AUTOMATIC FOCUSING. The position of the lens panel is governed by a lever following a cam. At high degrees of enlargement (top) this raises the lens panel; at low magnifications (bottom) it lowers the lens panel to increase the lens-to-negative distance for sharp focus. A, enlarger head. B, lens panel with lens. C, control lever. D, focusing cam.

Colour enlargers using an integrating and colour mixing system of this nature inevitably have to be diffused light enlargers. For colour work this is no drawback; even a directed light enlarger would yield no greater image contrast owing to the very small light scattering ability of the dye images. Comparatively intense lighting is, however, necessary to yield practical exposures, since part of the light is filtered out by the colour control filters. Colour enlargers therefore generally work with one or more high intensity lamps. They also need adequate ventilation to prevent overheating which would damage both the filters and the colour negative.

Enlargers for commercial colour printing may incorporate considerably more complex lighting and colour control arrangements.

Electronic Enlargers. The enlargers described so far use a continuous and uniform light source that simultaneously and evenly illuminates the whole negative area. By contrast, so-called electronic enlargers use a flying spot scanner—an electron beam moving over the surface of a cathode ray tube—as the light source. This exposes the image spot by spot, like the scanning system of a television screen, and not all at once. During the exposure the

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

scanning beam moves over the whole negative area in an intricate pattern which ensures that the spot passes over every point of the negative for the same length of time.

An important characteristic of this system is that the intensity of the electron beam can be controlled according to the density of the negative area that the beam passes over at any instant. For this purpose the light coming through the negative is monitored by a photo cell system, the output of which is fed back into the circuit controlling the scanning spot intensity. With no feed-back, the spot would remain uniformly bright all the time, as with a continuous light source. With 100 per cent negative feed-back, the spot intensity automatically compensates for variations of negative density and the resulting print would be uniformly grey. Intermediate degrees of feed-back yield prints of lower or higher contrast, so that negatives of varying degrees of contrast can be printed on a single grade of paper. Moreover, this system of contrast control can reduce the overall tone range of the negative image, without reducing the detail contrast to the same extent.

Hence prints produced in an electronic enlarger reproduce all the fine detail even of very contrasty negatives without exceeding the contrast range of the paper. The effect of the flying spot scanner exposure is that of an unsharp contrast reducing mask—virtually a luminous positive low contrast image of the negative being printed, and produced during the printing exposure.

The photo cell system can also register the total light passing through the negative and cut off the exposure when sufficient light has passed to produce a correctly exposed print. Both the contrast (feed-back) and exposure level are usually adjusted by calibrated settings of the control circuits.

Electronic colour enlargers working on similar principles use in addition cyan, magenta and yellow filters in front of the monitoring photo cell, and red, green and blue filters in front of the enlarger lens for three successive exposures. The cyan, magenta and yellow filters in turn analyse the red, green and blue content of the light coming through the colour negative and control the exposure accordingly through the three printing filters.

ENLARGING

Projection printing or enlarging on development papers requires suitable equipment.

Exposures must be found by trial or measurement, and the prints go through a standard routine of development and fixing.

Large quantities of enlargements of the same size can be made from the same, or similar, negatives at about the same rate as they can be printed by contact. But the rate is far less for prints of different sizes from different negatives where separate exposure tests are necessary.

The prints can be made in any size or format, and from the whole or part of the negative. In projection printing the appearance of the finished print can be controlled within wide limits by the choice of paper surfaces, individual technique, and the use of accessory equipment. Special devices, like image distortion and combination printing, can be employed.

The image colour can be black, or warm-black to red-brown with warm-tone papers. Toning processes can produce any other colour.

Enlarging papers are made in a number of grades, so that acceptable prints can be made from negatives of almost any contrast.

Enlarged prints are made by projecting the negative image on to the printing paper through an enlarger. Many enlargers can be used for same-size printing, and some even for reduction, e.g., for making lantern slides or film strips from larger negatives.

Enlargements are usually made on bromide or fast chlorobromide paper. Such papers are sensitive to ordinary artificial lighting or daylight and must be handled and processed only under an orange or olive-green safelight.

SETTING UP THE ENLARGER

The steps in making enlargements fall into two basic operations: setting up the enlarger, and making the exposure—after which the print is processed.

When setting up the enlarger, it is quicker and better to follow a routine procedure.

Sorting the Negatives. Negatives for enlarging must be selected even more critically than for contact printing. Slight unsharpness that passes unnoticed in a contact print shows up distinctly in an enlargement, and pinholes, grain, scratches, and other flaws become much more noticeable. A good negative, having had the correct exposure and correct development, will be of moderate density and contrast, and generally of fairly fine grain. Excessive negative exposure and development tend to increase contrast and grain. Grossly under-exposed negatives cannot yield perfect enlargements as essential shadow detail is missing.

The contrast in a negative can be controlled in enlarging by choosing the appropriate grade of paper, and the print density is, of course, determined by length of exposure.

By carefully examining the negatives under a

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

SEQUENCE OF ENLARGING STAGES. 1. *Sort out the negatives, discarding any that are unsuitable for enlarging due to obvious faults.* 2. *Place the selected negative in the carrier.* 3. *Adjust magnification and focus of the enlarger.* 4. *Make a test strip to establish the correct exposure necessary.* 5. *Locate printing paper on baseboard (e.g., by means of a suitable masking frame), and expose for the time suggested by the test strip after development.* 6. *Process the exposed enlargement (develop, rinse, fix, wash, and dry).*

magnifying glass, or even by projecting them in the enlarger on to a white sheet on the baseboard, they can then be graded in contrast and density groups.

NEGATIVE CONTRAST AND PAPER GRADE

Negative Contrast	*Appearance of Highlights*	*Negative Shadows*	*Paper Grade*
Very low	Very similar in density usually fairly thin		Ultra hard
Low	Medium	Thin	Hard
Medium	Normally dense	Thin but full of detail	Normal
	or		
	Very dense	Medium	
High	Dense to very dense	Fairly thin but full of detail	Soft
Extreme	Very dense, almost blocked up	Thin, may lack detail altogether	Extra soft (negative frequently unprintable)

Under-exposed negatives appear thin and soft (unless greatly forced during development) since the maximum image density is low by comparison with the fog level. Printing on a hard paper grade will distort the tone scale, but is the only way of producing a reasonably presentable print.

For judging both contrast and density a useful aid is a collection of standard negatives of the appropriate contrast groups and of four or five degrees of density. After ascertaining the correct paper grade and a relative exposure for each, these can be mounted between glass. Such a set will serve for direct comparison with any new negative to be printed. In estimating the negative quality, the film or plate is best observed against a well diffused light source (e.g., a light box or the light reflected from a pale coloured wall), holding the negative at the same distance from the light every time. Observation against a direct source (such as a bare lamp) is misleading.

An alternative method of judging the image is to lay the negative down on a page of a book printed on white paper. A normal negative of average contrast should show good tone and detail, with some density even in the thinnest parts, and the text underneath should be just readable through the densest areas. Similar examination of other negatives will show whether the highlight density (which can be used to estimate exposure) is higher or lower. It will also show whether the contrast (as indicated by relative density of highlights and shadows) is greater or less.

Usually it will be possible after some experience to dispense with most of these aids to judging negatives.

Loading the Negative Carrier. Before loading, both the negative and the glasses (if any) of the negative carrier should be cleaned to remove as much dust as possible.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

NEGATIVE AND PAPER CONTRAST. To obtain a well-graded print, the paper contrast used must be matched to the negative gradation. Top left: *Contrasty negative with very dense highlights and thin or very thin shadows. This needs a soft paper grade to accommodate the full density range. With a normal paper the result would be distinctly hard, and with a hard paper the image would be almost devoid of tonal gradation.* Centre left: *Normal negative showing average tone scale. This will yield the best print on medium or normal paper grade.* Bottom left: *Soft negative with comparatively small tone differences between even the extremes of light and shade in the subject. A hard (and sometimes extra hard) paper grade is required to separate the tone values.*

Glass surfaces are best cleaned with a soft cloth or chamois leather. If the glass is breathed on and the film of moisture appears quite even without any streaks or patterns, the surface can be accepted as being clean. Rubbing and polishing glass has the undesirable effect of charging it with static electricity and making it attract dust particles. So immediately before use, the negative and each glass surface is gently dusted with a clean, soft brush specially kept for the purpose, and then wiped over with the dry ball of the thumb. This discharges any static electricity on the surface, and removes the last traces of dust.

The details of the loading procedure depend on the design of the negative carrier.

The negatives are inserted with the emulsion side facing the lens. If they are loaded wrong side down, the projected image will be reversed left to right, but it will not suffer in any other way. The image may be deliberately reversed in this way for better pictorial effect so long as the picture does not contain anything that obviously reveals the trick, e.g., lettering.

The edges of the negative should be completely masked in the carrier so that no stray white light can fall on the base-board.

Some enlargers incorporate adjustable masks which can be moved in or out to mask off the negative area required.

Focusing. With focusing enlargers where the image size is adjustable, the picture has to be focused for each size of enlargement. This is done in much the same way as on a camera by moving the lens forwards and backwards until the image appears sharp.

The image is observed on a sheet of white paper held exactly where the bromide paper will be held when the enlargement is being made. It is absolutely necessary for the surface of the white paper to occupy the same position as the emulsion of the bromide paper, so that the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

image on the final print will be sharp. If any type of paper holder or masking frame is used for the bromide paper, it must also be used to hold the paper on which the image is focused.

The enlarger head is moved up or down the column until the projected image of the negative (or the selected part of the negative) is about the right size. The lens is then focused until the image is reasonably sharp, and the size of the picture is checked. If it is too large, the enlarger head is lowered; if too small, it is moved up the column and the image is again focused sharply.

For fine focusing, the lens is moved until the image just passes the point of maximum sharpness. This position is noted and the lens is moved in the opposite direction until the image again just begins to be unsharp. By successive up and down movement, these limits of sharpness are brought as close together as possible. Finally, the lens is set half-way between the two limits.

There are several devices available for getting over the difficulty of focusing dense or flat negatives where the image is either too faint or not contrasty enough to be seen clearly. Such devices are called focusing aids.

There are two kinds of focusing aid: separate accessories and built-in devices.

The accessories include focusing negatives and ground glass viewing devices.

A focusing negative is a piece of black film carrying fine transparent lines, crosses and circles, extending over the whole negative area. The clear, distinct lines are easy to focus, and once the position of maximum sharpness has been found, the negative is removed and the film or plate to be enlarged is inserted in the carrier in its place.

Provided that nothing is allowed to shift when the substitution is made, the resulting enlargement should be the sharpest that can be made from the negative.

Screen focusing devices usually consist of a stand which holds a mirror and a ground glass screen. When the stand is placed on the surface of the paper on the enlarger easel or in the paper carrier, the mirror reflects part of the image on to the ground glass screen. The screen is set at a convenient angle for viewing, and the dimensions of the device are arranged so that the distance travelled by a ray of light falling on the ground glass surface is exactly equal to the distance it would have travelled if it had been allowed to fall on the surface of the paper. So if the image is sharply focused on the screen, it will also be sharp on the print. Most focusing devices of this sort incorporate a focusing magnifier.

Another focusing accessory consists of a strip of black paper mounted in a holder to fit over the centre of the lens. The two halves of the lens each form distinct images. These two images merge into one when the negative is accurately focused.

Some enlargers have a calibrated scale on the column, and a second scale on the lens mount or on the focusing rack. When both scales are set to the same value, the lens is sharply focused. The enlarger head is set for the required magnification against the scale on the column, and the lens is then set to the same figure.

Other enlargers are equipped with a built-in rangefinder. This projects two spots of light on to the baseboard and the image is focused by adjusting the lens until the spots coincide.

Sharpness meters can also be used to determine the position of optimum sharpness of the image on the baseboard. The image is here focused on a photo cell or set of photo cells, and the output observed on the measuring instrument while adjusting the lens focus. The maximum reading of the measuring needle indicates the position of maximum sharpness.

Automatic enlargers cut out the whole procedure of focusing. They are set once only for the lens to be used. After that, raising and lowering the lamphouse increases or decreases the picture size, and focuses the image at the same time. L.A.M.

Same-size or Reduced Prints. The enlarger can be used not only for its basic purpose of producing larger size pictures but also to make prints of the same size as the original negative, or even to a reduced scale.

This method is valuable when it is necessary to be able to hold back or bring out certain portions of the negative by dodging or any other method of control to which contact printing does not lend itself. In enlargers which have bellows or focusing mounts where the total extension between lens and negative is twice that of the focal length of the lens—e.g., giving a 6 ins. extension with a 3 ins. lens—it is possible, without any further aids, to project an image the same size as the negative on to the baseboard. Many enlargers, however, do not cater for this long extension. In most instances this can be overcome by inserting an extension tube between lens and lens panel.

If a reduced size print is required—e.g., when making photographic miniatures—an even longer extension is necessary. While it is possible to provide this by inserting an extension tube between the lens and lens panel, the method may be limited by either the diameter of the lens mount or of the extension tube. One of these may cut off the corners so that the whole of the original negative is not reproduced. The amount of extension from negative to lens required when reducing the negative to give an image one-half smaller is equal to three times the focal length of the lens. To reduce a negative to one-third of its original size an extension of four times the focal length is needed.

The easiest way of getting reductions without extension tubes is to use a lens of shorter focal length. This needs less extension and has sufficient covering power for the whole negative when used at more than double-extension.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The above methods of printing same-size or on a reduced scale are useful when making transparencies from larger negatives—e.g., to suit a miniature projector. It is only necessary to substitute lantern plates or positive film for the paper on the baseboard. W.D.E.

EXPOSURE

In enlarging, the correct exposure is usually found by the aid of a test strip, a step wedge, a photometer, or by density measurements carried out on the negative.

Test Strips. Exposure is generally determined by making a test strip. For this, a piece of the actual paper on which the enlargement is to be made is exposed in sections on the enlarger base. Each section is given a longer exposure than the one before, and the correct exposure is based on the appearance of the developed strip of paper.

Procedure. (1) The enlarger is adjusted for the required print size, and the negative is focused in the normal way.

(2) The orange filter is placed over the enlarger lens and a strip of the enlarging paper to be used is held flat on the base-board where it includes the most important part of the image. (A part should be selected with as full a range of tones as possible, from the brightest highlights to the deepest shadows, over the whole length of the strip.)

(3) The orange filter is swung out of the way, and the whole strip exposed for, say, 2 seconds.

(4) The enlarger lamp is switched off, and half an inch or so of the strip is covered with an opaque card.

(5) The enlarger lamp is then switched on again for 2 more seconds.

(6) The above procedure is then repeated with increasing exposures of 4, 8, 16, 32, etc., seconds until the whole strip has been covered.

It is not necessary to switch off the enlarger between the test exposures. The opaque card can be moved along the strip at the required intervals, so long as the enlarging paper is not touched.

The whole strip has now received a series of exposures of 2, 4, 8, 16, 32, etc., seconds. Thus each section of the strip receives twice the exposure of the section before it.

After processing the strip should show one correctly exposed step. Its exposure time is then the correct exposure for the final print.

Where the correct exposure lies between two consecutive steps, a second test strip may be made to cover this range only. Thus between 8 and 16 seconds, the intermediate steps would be 10, 12, and 14 seconds. This second strip pinpoints the exact exposure.

But if all the sections are too light, a further test strip must be made, starting at the last exposure on the old strip. If this gives an inconveniently long time for the correct exposure, the light must be increased by either

MAKING A TEST STRIP. Arrange a strip of the enlarging paper on the baseboard so that it covers a picture area with a wide range of image tones. Expose for 5 seconds, and cover up a small section of the strip with an opaque card. After a total of 10 seconds cover a further section of the strip, following up after 20, 40 and 80 seconds from the beginning of the exposure. After processing the strip should show one section of reasonably correct exposure. A further strip covering a narrow exposure range will pinpoint the exact time required.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

increasing the lens aperture or using a more powerful lamp in the enlarger.

If all the sections are too dark, there is no point in making another test strip with exposures shorter than 2 seconds. Exposures as short as this are normally much too short to be timed conveniently or accurately. The solution is to use a smaller lens aperture or a weaker lamp, and adjust matters to give a correct exposure of suitable duration.

Where the approximate exposure is known from experience, or can be arrived at by other means, one strip covering a narrower range is sufficient. For instance, where the exposure is known to lie between 8 and 32 seconds, use test steps of 8, 10, 13, 16, 20, 26 and 32 seconds.

Step Wedge Tests. The test strip can be produced in one operation by using a step wedge in the shape of a strip, circle, or square of film printed with sections of progressively increasing density. The density of each section is arranged so that the paper under it receives a known proportion of the total exposure.

The wedge is placed over a piece of the enlarging paper on the base-board, and the negative image is projected on to it for a fixed time—e.g., 1 minute. After processing the test piece should show one correctly exposed section. Once the section is known, the equivalent exposure that it has received can be easily calculated.

On some step wedges used for enlarging, each step is printed with the appropriate fraction of the total exposure that it gives. Sometimes each step carries a code letter which shows on a calculator disc the exposure equivalent to any over-all exposure.

If all the steps on the exposed test piece are too light or too dark, the over-all exposure is increased or decreased accordingly.

Exposure by Photometers. A grease-spot photometer can be made to give the correct enlarging exposure and paper grade. For this purpose it must be used in conjunction with a set of specially prepared grey scales, one of which must be made for every grade and type of paper used.

To prepare a grey scale, the enlarger is first adjusted (with no negative in the carrier) to give a standard photometer brightness reading on the easel.

A strip of each enlarging paper is then given a series of exposure steps as for a test strip. In this case each step is given about 1½ times the exposure of the one before: 2, 3, 4, 6, 8, 12, 16, etc., to 360 seconds. After processing, the strip should show a full range of tones from white paper to completely black. If the steps are all too light or too dark, the brightness of the illumination used for the grey scales will have to be increased or decreased accordingly.

The grey scales can also be made by exposing the paper under a step wedge, although most enlarging step wedges do not cover a wide enough range.

The grey scale is mounted on a card, and each step is marked with a tone factor. The tone factor is calculated by dividing the standard light strength as measured by the photometer by the exposure in seconds that the section has been given.

The contrast range covered by the strip and full particulars of the make and grade of the paper are written on the card. The contrast range is determined by taking the tone factor for the lightest tone—the first grey step—and dividing into the tone factor of the first full black: i.e., the contrast range is the ratio:

$$\frac{\text{Exposure given to first full black}}{\text{Exposure given to first grey scale step.}}$$

Determining Paper Grade. The negative is focused in the enlarger in the usual way and the brightness of the lightest and darkest parts of the projected image is measured with the photometer.

The ratio of these two brightness readings is a measure of the contrast range of the negative.

The grade of paper needed to include all the tones of the negative must have the same contrast range as the negative. So once the ratio has been measured, it is only necessary to pick out the grey scale with the same contrast range; the grade of paper on which the grey scale is printed will be the correct grade for the negative in the enlarger.

When using variable contrast papers, determination of the paper grade in effect involves finding the best printing filter to use, or the most suitable ratio of exposures through the two maximum and minimum contrast filters.

Alternatively it is possible to use a contrasty paper grade for all negatives, and to soften the gradation by a controlled preliminary fogging exposure. This technique is known as flashing. It is fairly widely used in commercial photo finishing, where automatic measuring systems determine the amount of flashing required for a particular gradation. In the amateur darkroom, flashing is less useful, since the pre-exposure must be exactly determined, and also be uniform over the whole print area. The degree of flashing for any required print contrast there must be determined by careful tests.

Determining Exposure. To find the exposure needed, the photometer reading for the darkest part of the negative is divided by the tone factor for the first grey step on the grey scale. The very lightest parts of the negative will then print black, with all the intermediate tones naturally falling into place.

For example, say the readings of a directly calibrated photometer for a negative are 120 in the darkest and 10 in the lightest areas. The contrast range is 12 : 1, and a paper with a grey scale which indicates such a contrast range—probably a grade 3 or hard paper—would be chosen for the print. If its highest tone factor is, say, 8, the correct exposure time needed is 120 ÷ 8, or 15 seconds.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

A new set of grey scales must be printed for each new batch of paper, because paper speeds may vary from batch to batch. And it is advisable to print new scales after every year or so that the paper is stored to allow for loss of speed with age.

Once the grey scales have been made, there is no need to make test strips or trial exposures. The method mainly relies on the accuracy of the photometer readings, and on rigidly standardized processing—i.e., full development in an accurately made-up standard developer. The same developer must be used for the grey scales as for the actual prints.

Use of Density Measurements. The correct exposure can be arrived at by measuring the range of densities in the negative by a densitometer, or specially adapted photo-electric exposure meter.

Density measurements made in this way can be used to determine both the exposure and the grade of paper needed to give an acceptable print from any negative. A set of standard test prints is made with a negative of known density and contrast. The standard prints relate the densities of the negative to actual print exposures at a given magnification and lens stop. From this information exposures at different magnifications and lens stops are calculated.

The relationship between the measured densities of the standard negative and any specimen negative is the same as the relationship between the exposure needed for any particular print in the prepared series and a similar print made from the specimen negative.

But the conditions in which such density measurements are made are quite different from those in an enlarger. The effective contrast range of the negative, for instance, is not necessarily the same as that measured by the densitometer. The difference depends largely on the enlarger illumination used; it may even call for a different grade of paper from that indicated by the densitometer readings.

Exposures at Different Magnifications. A change from one degree of enlargement to another demands a corresponding change in exposure time. The exposure must be increased when the scale of enlargement is increased, and vice versa.

The table below gives approximate values at different magnifications. It applies to normal condenser enlargers with semi-diffused lighting. With enlargers which have fully diffused illumination, the variation of the exposure time with the degree of enlargement is slightly greater.

Effect of Lens Stops. When the time for the correct enlarging exposure is inconveniently short for accurate timing—e.g., if it is 5 seconds or less—it can be extended by using a smaller lens stop. And exposure times at high magnifications can sometimes be shortened by opening up the lens aperture. But the change in exposure cannot be calculated by using the *f*-numbers marked on the aperture ring.

The optical system of some enlargers tends to direct more light through the centre than through the outer regions of the enlarging lens For this reason the light passed by the lens does not always vary in strict proportion with the size of the stop.

Some enlarging lenses have the stops marked in direct values: 1, 2, 4, 8, 16, in accordance with the actual measured amount of light that they pass at the various diaphragm settings. The numbers show the relative exposure at each stop without further calculation.

Where the lens stops are marked in *f*-numbers (which are not directly proportional to the light passed) the exposure times at the various stops can be found from the table above.

This table applies only to enlargers with semi-diffused or fully diffused illumination. With condenser enlargers which have a point

source of illumination the differences are smaller, and also depend on the degree of enlargement.

Checking the Paper Grade. The approximate paper grade is decided beforehand when the negatives are classified, but it must be checked by actual trial.

Once the correct exposure has been found by the method chosen, a small test piece or even the test strip itself will show whether the grade chosen is suitable. Different grades of the same paper usually require different exposures, so a second test strip will usually have to be made to find the correct exposure for the new grade.

Automatic Exposure Systems. Various semi-automatic and fully automatic exposure measuring devices can simplify the job of determining enlarging exposures. Most of them are based on the measurement of the light reaching the enlarging paper, and frequently incorporate some means of switching the enlarger lighting off when the paper has received enough exposure. The measurement takes into account the full negative area, and so requires certain over-riding adjustments for predominantly light or predominantly dark negatives. Also, separate adjustment is necessary for different contrast grades and paper types. The measuring arrangement generally uses a system of photo-multiplier cells.

A simple method is to measure the light reflected from the enlarging paper during the exposure on to a photo-multiplier cell. This may be fixed to or near the edge of the masking frame and oriented so as to cover the whole paper surface. The sensitivity of the photo-multiplier cell circuit is adjustable to allow for various paper speeds, and after preliminary calibration this system yields reasonably reliable exposures. On switching on the enlarger lamp for the exposure, the photo cell starts to charge up a capacitor system. When the latter is fully charged, a leakage current activates a further circuit which switches the lamp off again. Exposure control units of this kind must also be adjusted for the reflectivity of the paper surface, but automatically take into account the lens aperture and degree of magnification. Generally the photo cell is set to cover a specific paper size.

A second method uses a special masking frame with a transparent or translucent top, with one or more photo-multiplier cells arranged underneath. These cells then measure the light coming through the enlarging paper, and again control the exposure accordingly. In addition to adjustments for paper sensitivity, these masking frames have to be calibrated for the transmission characteristics of the paper base (single or double weight, etc.) and also for the print size—where this is adjustable. Masking frames of this kind may include sets of photo cells behind red, green and blue colour filters and so control the exposure or the filtration when making colour enlargements.

A third system measures the light coming through the enlarger lens—either via a beam splitter built into the enlarger or by a swing-out photo cell placed in position for measurement only. In the first case a proportion of the light is constantly diverted to a photo-multiplier cell and again controls the enlarging exposure as before. In the second case the photo cell is used for measurement of the light intensity only, and the reading transferred directly or indirectly to a suitable timer. This system requires a calibration adjustment for the paper speed and also for the degree of magnification, since the light flux through the lens does not vary a great deal with a change of enlargement.

Making the Exposure. The exposure is conveniently made by switching the enlarger light on and then switching it off at the end of the required time.

The paper is placed in the paper holder or

CC-0. Vasishtha Tripathi Collection. Digitized by Siddhanta eGangotri Gyaan Kosha. Digitized by eGangotri Digital Preservation Foundation, Chandigarh

masking frame and positioned with the lamp switched on and the orange filter in front of the lens. The lamp is then switched off, the orange filter swung out of the way, and the lamp switched on again for the exposure.

The most convenient way of controlling the exposure is by a timer wired into the enlarger lamp circuit. This is set to the appropriate exposure time, and the exposure started by pressing a switch or button. The enlarger light then remains on while the timer runs down, and automatically switches off at the end of the exposure. The automatic exposure control systems mentioned above include a timer (usually electronic) for this purpose.

With almost all enlargers there is a risk of vibration, certainly at high degrees of magnification. And if the enlarger head is moving in relation to the baseboard during the exposure, the picture will not be sharp. So it is advisable to allow time for any vibration to die down before switching on. For the same reason neither the enlarger nor the table it stands on should be touched or shaken during the exposure. Professionals, who use sturdy equipment and handle a great deal of work, expose by removing and replacing the orange filter, rather than switching the enlarger on and off. Continued switching is time-consuming, and also considerably shortens the life of the lamp.

Vibration can also be caused by people walking about in the room or on the same floor during the exposure (particularly if the darkroom is on an upper floor). It may even be necessary to cease enlarging temporarily while heavy traffic is passing in the street outside.

Shading and Spot Printing. If areas of the negative are too dark or light to print satisfactorily, the exposure that the paper receives may be selectively modified.

This is commonly done by cutting out cardboard of the desired shape and holding it over the paper during part of the exposure in the case of shading, or using it as a mask for additional local exposure in the case of spot printing. With both methods, the card must be moved slightly during the exposure to avoid printing as a sharp edge. The hands can also be used for shading.

With electronic enlargers shading can take place automatically to pre-determined degrees.

LARGE PRINTS

Most enlargers are designed to give enlargements of at least 12 × 15 ins. from the whole negative with the lamphouse at the top of the column. This size is as big as most amateurs normally wish to print, but occasionally they may want to make an enlargement bigger than this, or to enlarge only a part of the negative to this size. In either event, if 12 × 15 ins. is the normal limit of the enlarger, some special arrangement must be made to increase the scale of reproduction. There are two ways of doing this: by using a lens of shorter-than-normal focal length, and by increasing the lens-to-paper distance.

Short Focus Lens. The scale of enlargement can be increased by substituting, say, a 2 ins. (5 cm.) lens in an enlarger normally designed for a 3 or 4 ins. (7·5 or 10 cm.) lens. But it must be possible to bring the lens to within 2 ins. of the negative, and if the focusing scale does not permit this, the new lens must be fitted in a recessed adaptor on the lens panel. Often this arrangement means that the iris diaphragm control is out of reach of the fingers and a special adaptor has to be added to make adjustment possible.

But even when the negative can be focused, if the new lens is a normal type its shorter focal length will also mean that it will cover a smaller area of the negative. So the arrangement will not work if the whole of the negative is to be enlarged. To enlarge the whole negative, a wide angle lens would be required—i.e., one with a covering power greater than that of a normal lens of the same focal length.

The arrangement has other drawbacks—e.g., the focal length of the condenser will no longer accord with the new negative-to-lens separation, and the lamp may be too close to the condenser. In theory these factors upset the even illumination of the negative, but in practice the lamp can generally be adjusted, or provided with extra diffusion, to give reasonably uniform lighting over the whole area.

A 2 ins. (5 cm.) lens used in this way in an enlarger normally designed for a 3 ins. (7·5 cm.) lens would give a picture 1½ times bigger than normal each way—i.e., instead of a 12 × 15 ins. picture, the new size would be 18 × 22½ ins. (46 × 57 cm.).

Increasing Lens-Paper Separation. The height of the enlarger column sets the limit on the size of the enlargement that can be made with a given lens. But there is no limit to the size so long as the paper can be placed far enough away from the lens. Most enlargers are designed so that the enlarger head can be swung around through 180° on its column to allow the image to be projected off the baseboard for this purpose. The baseboard is weighted—e.g., with a pile of books—and the enlarger is placed near the edge of the table or bench with the head pointing down at the floor. The paper is then either exposed on the floor or, if the separation is too great, on a box or similar flat object.

Some enlargers are made so that the head can be turned to project the image horizontally. In this case the paper is either pinned to at board or sheet of card against the wall, or held in the type of easel manufactured for use with horizontal enlargers.

When big enlargements are made in this way, the risk of blur from vibration is greatly increased because the effect of relative movement between lens and paper increases in pro-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

portion to the separation and because less power of the light by fitting a more powerful and paper are independently supported instead of being on a single rigid structure.

The moral is simply to take every possible precaution against movement during exposure. If the lamp switch is on the enlarger instead of in series with the flex, there is always a risk that switching on will set the head vibrating. So it is wise to hold a piece of black card in front of (but not touching) the lens for some seconds after switching on the lamp, and then to make the exposure by uncovering and covering the lens with the card when everything has settled down. And unless the darkroom has a concrete or similar type of solid floor, no one should walk about during the exposure.

Exposure. The exposure for big enlargements is apt to be lengthy because the intensity of the light falls off in proportion to the square of the distance between the lens and paper—i.e., doubling the distance calls for a four times increase in exposure. During a long exposure there is a greater risk of accidental movement, and any light leaks or unsafe darkroom lighting are more likely to fog the paper. So it is as well to keep the exposure as short as possible by other means.

One way is to make the exposure at the widest lens aperture that will give sharp definition over the whole picture area. If only a part of the negative is being enlarged in the centre of the field it may not be necessary to stop the lens down as far as when enlarging the whole of the negative. This is because the definition of the lens over the central part of the field is fairly even; falling off only becomes serious towards the outer region of the field.

Another useful expedient is to increase the high-efficiency lamp.

When using a light as intense as this in the enlarger lamphouse, greater care than usual must be observed in sealing off light leaks and covering up any light or polished surfaces that might reflect the glare from the printing paper back on to it again. It is also advisable to have the paper resting on a sheet of matt black paper to absorb any light falling outside the actual image area. Finally it should be remembered that it will be unwise to trust the red safe screen normally used in front of the enlarger lens for checking the image.

PROCESSING

When the print has been exposed under the enlarger, it only remains for it to be processed in dishes.

The sequence involved in processing the print is: develop, rinse, fix, wash, dry. The actual solutions employed may vary according to certain requirements, but in general they will consist of a standard print developer, plain water or an acid stop-bath for the rinse, and an acid-fixer for the fixing.

When dealing with large prints, a special procedure is used if the correct size dishes are not available for processing. L.A.M.

Books: *How to Make Your Own Enlargements*, by L. Gaunt (London); *Enlarging*, by C. I. Jacobson (London); *The Complete Art of Printing and Enlarging*, by O. R. Croy (London).

ENLARGING BACK. Attachment which is fitted in place of the plate holder on a plate camera, enabling the camera to be used as an enlarger. The device consists of a negative carrier and an illuminating system including a diffuser and lamphouse. A modern version of this fitting employs a cold cathode grid illuminant which cuts down the bulk and eliminates the diffuser.

ENLARGING FILTER. Enlargers of all types are usually fitted with a coloured filter. This can be slipped on to the lens or brought in front of it so that the position of the image on the bromide paper can be checked before exposure without fogging the paper.

The filter is made of glass, gelatin, or plastic, coloured either a deep brown or medium red. The material may be fitted into a slip-on mount, like a colour filter, or it may be hinged or pivoted so that it can be swung into position without touching the lens (this is the better method as there is no risk of moving the lens).

Such filters are not safe over a long period; they are intended only for a brief check, nor should the image be focused on the paper with the filter in position because the lens may not focus the visible, non-actinic red rays and the actinic blue rays in the same plane.

The holder for the filter may allow the filter to be changed. This is useful when special filters are needed for other reasons—e.g., correcting colour balance when making colour prints.

Colour filters which slip over the lens of the enlarger are used when enlarging on variable contrast paper. This type of paper yields soft or hard print gradation according to the colour of the printing light. Filters for contrast control are normally of gelatine and are supplied in a cardboard holder, but for regular use they can be bought mounted between glass in metal mounts.

See also: *Colour printing technique; Enlarger; Variable contrast papers.*

ENLARGING LENS. The lens used in an enlarger must be capable of giving a critically sharp image with a perfectly flat field. A lens

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

intended for colour enlargement must, of course, be fully colour-corrected. Good colour correction is still desirable for black-and-white enlarging as well, since chromatic aberrations lead to unsharpness. This is particularly important with enlargers using tungsten and cold cathode lighting alternately.

With enlargers working exclusively with mercury vapour or other lamps rich in ultra-violet radiation, the lens should be corrected for these short wavelengths. Otherwise the lens may have to be refocused after visual focusing (since the eye is most sensitive to the medium wavelengths of the visible spectrum). On some specialist enlargers this is done automatically, for example when a yellow viewing filter is swung out of the optical path.

Using the Camera Lens. While some camera lenses will perform reasonably well as enlarging lenses, they are never ideal. A camera lens is computed for short lens–film and long lens–subject distances. This is exactly opposite to the enlarger lens which works with long lens–film (paper) and short lens–subject (negative) distances. Sometimes an improvement in image quality can therefore be obtained by mounting the camera lens back to front in the enlarger, with the front (from the camera aspect) facing the negative.

A three or four element anastigmat is generally satisfactory for normal enlarging. If a camera lens is used to save the cost of a separate lens, it should be of symmetrical or almost symmetrical construction. At the same time, lenses of high-class miniature cameras are frequently used and give good enough results for all normal requirements.

Focal Length. The enlarging lens must be able to cover the full negative area with which it is intended to be used. Generally an enlarging lens of the same focal length as the normal camera lens (in other words roughly equal to the diagonal of the negative format) is satisfactory.

A slightly longer focal length—for example 60 mm. instead of 50 for 35 mm. negatives, or 90 mm. instead of 75 mm. for $2\frac{1}{4} \times 2\frac{1}{4}$ ins. square formats and so on—is frequently popular. By not extracting the maximum covering power of the lens it is frequently possible to obtain a better average definition, especially at full aperture.

Where an enlarger is used for several negative sizes, for example 24×36 mm. and $2\frac{1}{4} \times 2\frac{1}{4}$ ins., it is more convenient to have two enlarging lenses, one for each format. While the longer focus lens could be used for the smaller negative size, it necessarily limits the maximum degree of magnification obtainable from a given enlarger.

A short focus enlarging lens can on the other hand be used with larger negative sizes where very low degrees of enlargement or even reductions are required. Thus a 50 mm. enlarging lens can under these conditions be used safely with a $2\frac{1}{4} \times 2\frac{1}{4}$ ins. or even a $2\frac{1}{4} \times 3\frac{1}{4}$ ins. negative. At the great lens-to-negative distances required for same size copying or reduction the image angle covered by the lens is reduced.

Heating Up. When a condenser is used to focus the light from the lamp on the lens, it also concentrates the heat on it. This is one reason why it is better to use a lens specially designed for enlarging instead of one primarily intended for taking the photograph. Enlarging lenses are made without cemented components, whereas one or more glasses of a camera lens are frequently stuck together with cement which is softened by even a moderate rise in temperature. The risk to the lens can be eliminated by interposing a heat-arresting filter between the lamp and the condenser. A heat filter, composed of slips of Chance ON20 glass, safeguards the lens and is also a great help in preventing the heat from buckling or damaging the negative. This risk is greater with older lenses; some of the more modern types, even if cemented, use cements of greater heat resistance.

Maximum Aperture. The maximum aperture of the enlarging lens depends on the scale of enlargement it will be used for. Miniature negatives need very much more enlargement than, say, half-plate negatives, and so the lens used needs to be able to pass more light to keep exposure reasonably short when making big pictures. For this reason 35 mm. enlargers are commonly equipped with $f3{\cdot}5$ lenses, while enlargers for $2\frac{1}{4}$ square, or $2\frac{1}{4} \times 3\frac{1}{4}$ negatives have $f4{\cdot}5$ lenses and half-plate and over sizes have lenses often no more than $f6{\cdot}3$.

Stops. At times it is necessary to stop the enlarging lens down from the maximum aperture, and since in the darkroom it is difficult to see the stop values, so-called click-stops are now common. The iris setting ring is fitted with a leaf spring which clicks into notches corresponding with the various aperture settings. Any value can thus be located by the feel or the sound of the clicks as the ring is turned from the fully open position.

The stop values on an enlarging lens are not usually calibrated as for a camera lens—i.e., $f5{\cdot}6$, $f8$, $f11$, and so on—since this would mean that the first step on the majority of lenses would be less than a whole stop. This would be confusing, so the lens is sometimes marked 1, 2x, 4x, 8x, and so on, each step calling for twice the exposure of the one before.

In a condenser enlarger with a small light source, stopping down the enlarging lens does not necessarily bring about a proportional decrease in illumination on the easel. This is because the condenser frequently concentrates the light on to an area in the lens that is smaller than the maximum aperture. In other words, only a small central portion of the lens is being used. Until the area of the iris is reduced below the illuminated area of the lens, there is no significant reduction in the illumination on the easel.

Coated Lenses. All modern enlarging lenses are

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

now bloomed (coated on their glass surfaces with metallic fluorides) to reduce the amount of light lost by reflection and to prevent degradation of the image by scattered rays. When the lens is not coated, this stray light spreads an even veil of fog over the whole print which makes little difference to the shadows but greys the highlights and flattens the contrasts of the print. The increased contrast given by a coated lens is not enough to affect the paper grade which will be used, but it improves the definition of the print. This is because the contrast of the finer details is not blotted out by light scattered inside the lens.

ENPRINT. Fixed-ratio enlargement produced from the whole of a negative in an automatic large-output printer. Since the production of enprints requires little or no more time than that of contact prints, photo-finishers often offer such fixed-ratio enlargements at the same (or only slightly higher) prices as contact prints—and well below the price of normal enlargements. Originally enprints were offered as $3\frac{1}{2} \times 4\frac{1}{2}$ ins. enlargements from 24 × 36 mm. miniature negatives; nowadays similar fixed-ratio enlargements are available from a number of other negative sizes up to about $2\frac{1}{4}$ in. square and under various trade names.

See also: *Sizes and packings; Wholesale photo-finishing.*

EPIDIASCOPE. Projector which combines the functions of an episcope and a diascope in the one apparatus.

See also: *Projector (still).*

EPISCOPE. Optical projector for showing an enlarged image of small opaque objects, photographs and printed matter. By employing an episcope, a lecturer or teacher can show small objects conveniently to audiences.

See also: *Projector (still).*

EPSTEAN, EDWARD, 1868–1945. American photo-engraver. Writer and translator of articles and books on the history of photography, collector of books on photography and photomechanical work. Donated this collection to the Library of Columbia University, New York.

EQUIVALENT FOCUS. Distance between the nodal point and its corresponding principal focal point on the axis of a lens. Same as focal length.

EQUIVALENT WEIGHT. Term used in chemistry to denote the weight of any given substance that will either unite with one gram of hydrogen or displace it from a compound. The equivalent weight of any substance can be either measured or deduced, and it is possible, by equating the equivalent weights of the chemicals taking part in a reaction, to describe both the reaction and its products in quantitative terms.

See also: *Chemical calculations.*

EREMIN, YURIY PETROVICH, 1881–1948. Russian landscape photographer, from 1931 lecturer at the Moscow Architectural Institute and the Institute of Artistic Design. Documented Moscow's architectural reconstruction.

ERFURTH, HUGO, 1874–1948. German portrait photographer in Dresden from 1896 onwards, making only gum prints and later oil-pigment prints. In the 1920s he was the most celebrated photographer of the German intelligentsia. Moved to Cologne in 1934, where he was active until bombed out in 1943; his work survived in a bank safe.

ERNEMANN, HEINRICH, 1850–1928. German camera manufacturer. He induced the German government to endow a professorship of photographic chemistry at the Technical College in Dresden (filled by Dr. Robert Luther). His firm (and others) were merged, in 1926, into the Zeiss-Ikon A.G. In 1925 introduced the Ermanox camera with the Ernostar *f*1·8 lens, then the fastest camera.

ETHER. Diethyl ether; sulphuric ether. Solvent for many purposes, including making collodion emulsions.

Formula and molecular weight: $(C_2H_5)_2O$; 75.

Characteristics: Volatile pleasant smelling liquid. Very inflammable.

Solubility: Partially miscible with water.

ETHYLENE DIAMINE TETRA-ACETIC ACID. (E.D.T.A.) Used in developers, usually as the tri- or tetra-sodium salt, to prevent hard water precipitates. It is more stable than Calgon in strongly alkaline solutions. Also used in the compounding of combined bleaching and fixing baths (blix baths) from hypo and the ferric-EDTA complex. Sold under various trade names, e.g. Sequestrol (Geigy).

Formula and molecular weight: $(NC_2H_4N)(CH_2COOH)_4$; 292.

Characteristics: White crystalline powder. One of a group of chelating compounds which are able to form stable, soluble compounds with a number of metals such as calcium, magnesium, iron, etc. Certain metals, such as iron and copper, if present as impurities in developer chemicals, will tend to act as oxidation catalysts in the presence of E.D.T.A. and can cause accelerated exhaustion and aerial fogging.

Solubility: Sparingly soluble in acid solutions below pH 6 and more freely soluble in alkaline solutions.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

EVANS, FREDERICK HERMAN, 1852–1943. English professional photographer from 1898, previously a bookseller in the City of London and an amateur photographer for sixteen years. Member of the Linked Ring, 1901. Best known for his photographs of English cathedrals and French chateaux taken for *Country Life*. Also took many fine portraits of his artistic and literary friends. Gave up photography when platinum paper became unobtainable during World War I.

EVER-READY CASE. Carrying case, usually leather or plastic, which can be opened to give access to all the camera controls without being removed from the camera. The base of the case is generally fastened to the camera by a knurled screw which fits the tripod bush on the camera body and is threaded to take a tripod screw.

See also: *Case*.

EVERSET SHUTTER. Generic term for all shutters of the type—common on cheaper cameras—in which one movement of the release control tensions the shutter operating spring and then fires the shutter so that no separate cocking control is needed.

EVIDENCE BY PHOTOGRAPHS. The purposes for which photographs are produced in evidence in legal proceedings are broadly:

(1) To provide a record of something that it would otherwise be difficult or impossible for the Court to see—e.g., scenes of serious crime as they appear before anything has been disturbed; vehicles which have been involved in collisions, photographed before any repair or salvage has been done; roads, buildings and other distant places which may be many miles from the Court; injuries which will have healed and be no longer visible by the time of litigation; copies of documents, the originals of which cannot be made available.

(2) To present the results of an experiment or test (in many cases made in a laboratory) that it is not practicable to demonstrate in Court—e.g., photomicrographs; photographs taken by ultra-violet fluorescence; photographs illustrating some test or measurement; comparison photographs demonstrating the similarities between finger-prints, footprints, tool marks, fired bullets or cartridge cases, etc.

(3) To show something that only photography can reveal (infra-red photographs and photographs taken with unusual filters).

This article is not concerned with how such photographs are taken; it deals only with their use as evidence in the Courts.

Presentation. There must be no handwork on either negatives or prints to be used in evidence. Simple shading control during printing is permissible, and often indeed essential. But there must be no spotting, even where the filling up of a pinhole or two could not possibly lead to any misrepresentation. It is a legal axiom that not only must justice be done, but that it shall be manifest to all present that justice is being done. In the same way photographs should not only be free from faking; it must be clear that there could be no possibility of faking.

First and foremost, this calls for clean working in the darkroom. But if in spite of it the negative or print shows a flaw, the flaw must remain, and must be disregarded or explained in Court as need arises.

There should be no reconstruction of the scene for photography. No attempt should be made to replace anything inadvertently displaced. The photographer should simply record what is in front of his camera and explain, if necessary, any discrepancy between what the photograph shows and what witnesses describe.

There is no room for ingenious technical tricks in this field; the mere fact that photographs are being used to illustrate points of evidence implies a belief that the camera cannot lie, so all work should be as straightforward as possible. (Photographs produced under laboratory conditions of subjects normally invisible to the human eye are, of course, excepted). And the photographer should always assume that, while the members of the Court may know everything about the law, they know little or nothing about the technicalities of photography.

The following example illustrates this point: in a legal dispute over a road accident, one side produced photographs showing the view which the defendant would have had round a bend if he had been driving on his correct side of the road. The pictures were taken with a lens of normal focal length (i.e., 45–50° angle of view). The other side objected that there were only thirteen white-line dashes visible in the pictures, although it was agreed that there were in fact seventeen dashes between the camera position and the turn of the road. It required considerable explanation to establish that the photographs were a fair and accurate representation of what the defendant should have seen, and that no photograph could ever show all the foreground in front of the camera position unless the lens had an angle of view of 180 degrees.

Similar difficulties can also arise from the use of photographs of scenes artificially lit—e.g. streets at night. A lay court will expect the photographs to show neither more nor less than an eye-witness could have seen. They will not usually be able to appreciate the effect of the cumulative sensitivity of the photographic emulsion, by which the amount of detail recorded in a photograph of a dimly lit scene depends entirely on the exposure time.

Court Procedure. The usual procedure for taking the evidence of a photographer witness runs something like this. First he takes the oath (unless he has conscientious objections to

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

doing so, when a form of declaration may be substituted) and gives his name and profession or official status. He then states where, when and of what he took the photographs, that he made prints, which he produces, and that the negatives are in his possession. (He should take the negatives with him for inspection if requested, but they are rarely asked for.) He will then describe what the photograph, or each photograph of a series, shows. Finally, he may be cross-examined to bring out any point that the other side feels will be to their advantage. (The "other side" simply means the side that did not call him as a witness).

There is no recognized standard type of print for use in evidence. Single prints may be mounted on thin card with a brief descriptive caption. A series of photographs may be printed with a wide margin on the left-hand side, and then numbered and bound together bookwise in a light cover with a page of descriptive captions at the beginning.

The size of prints which should be produced depends on two things: perspective considerations, and the fact that they will be examined in the hand. The perspective should be as far as possible correct when the picture is held at the normal viewing distance. Prints should also be of a size convenient to hold. The size meeting both requirements best is generally something between 5 × 4 ins. and 12 × 10 ins.

The number of copies produced depends on the type of Court hearing the case. Where there is no jury—e.g., in a Magistrates' Court, County Court or before a Coroner sitting without a jury—four copies should suffice: one copy for each side in the case, one for the Bench and one for the witness himself to refer to. In trials by jury twelve copies are needed.

Captions. Captions must be rigidly factual and descriptive; there must be nothing to imply the conclusion which one side or the other is seeking to establish. In a road accident case it would be proper to caption a picture:

"View along the Weston–Eastwich road, taken from point A looking in the direction of B." A caption which added, ". . . showing that B is clearly visible from the correct side of the road at A," would be objected to by the Court, and the photograph might be declared inadmissible as evidence.

With photographs of a more technical type, such as are used to illustrate comparisons of finger-prints, tool marks, etc., it is permissible and indeed often necessary to indicate the important points by means of, for example, ruled lines or arrows. But if any of the indicating lines unavoidably obscure any detail, even unessential detail, there should always be a plain unmarked copy of the photograph for reference. H.J.Wa.

Book: *Photographic Evidence*, by C. C. Scott (Kansas City).

EXAMINATIONS. A few British professional and educational organizations hold annual examinations in photography. These examinations are usually intended for professional photographers but amateurs are also eligible. Such examinations confer certain diplomas or similar qualifications; they are not, however, needed by any person for carrying on photographic work.

The most important photographic examinations in Great Britain are those of the Institute of Incorporated Photographers and the City and Guilds of London Institute. Employers normally accept a pass in either of these examinations as evidence of ability and some firms make it an essential qualification.

Institute of Incorporated Photographers. The examinations of the I.I.P. are held in three grades: preliminary, intermediate and final, and they must all be taken in that order. The standard required for each grade is high and carries a practical test in addition to the normal written paper. The preliminary candidate must have an elementary knowledge of photography and be able to demonstrate it in practical tests. The intermediate examination requires a more thorough knowledge and practical ability in the general techniques of photography. The final examination may be taken in any of four different sections as follows: Commercial, Industrial and Advertising; Portraiture and Pictorial; Scientific Applications of Photography; Medical Photography. A high theoretical and practical standard is required in the section taken. In special circumstances candidates may be exempt from the preliminary and intermediate examinations.

Candidates must be capable of expressing themselves clearly and have a good general education. Past results show that many candidates fail because they lack normal ability in these respects.

City and Guilds of London Institute. These examinations fall into two grades—intermediate and final. The standard is approximately the same as that for the I.B.P. examinations. The intermediate consists of a written paper and a practical test; the final comprises a common written paper, a second written paper in either of two basic sections, and a practical test. A successful candidate who obtains a first-class certificate in at least one section of the final may later qualify for a full technological certificate by passing suitable external examinations in chemistry, physics and (sometimes) mathematics.

Other Examinations. There are examinations of a similar nature in other countries. More common, however, are the internal examinations of the various schools and colleges of photography throughout the world. These examinations are generally recognized in the absence of tests conducted by independent professional bodies. They follow a general pattern, but for internal examinations, atten-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

dance at the school is normally essential. In Britain, the examination at one of these schools carries exemption for the I.I.P. preliminary.

Various specialized bodies also hold examinations in their own fields—e.g., radiography, photo-mechanical printing and the photographic retail trade, etc.

As a suitable qualification, employers will sometimes accept Fellowship or Associateship of one of the leading photographic societies or institutes. This may again entail an examination, but normally the award is based on inspection of specimens of the photographer's work submitted, and on his past achievements.

Before offering himself for examination, the candidate should make sure that his experience is adequate. He may have taken a course in photography, not recognized by the examining body, which may not have covered an essential aspect. All examining bodies publish a syllabus of their examinations and sometimes copies of previous test papers. A close study of these will show the candidate if any gaps exist in his studies.

American Practice. There is no standard examination system comparable to that existing in England. The closest thing to it is the Civil Service Job classification breakdown which calls for tests in proficiency in the various categories. As a rule, these tests are based upon local arrangements for examinations; there is no completely standardized national procedure for this. J.D.C.

EXHAUSTION OF SOLUTIONS. The useful life of developing and fixing solutions is limited by a number of factors: the active ingredients become used up or they automatically decompose in the working solution, the solution becomes contaminated with impurities produced by the decomposition of the active ingredients, and certain solutions (developers) are oxidized by contact with the atmospheric air or air dissolved in the water.

Nothing can prevent the active ingredients from being used up during the actual processing, but the other causes of exhaustion can often be lessened by taking suitable precautions.

Water used in making up developers should be boiled for about five minutes to get rid of dissolved air. Chemicals should be bought in the smallest pack that will serve normal needs—it is not economical to buy in bulk if the chemicals deteriorate through being stored for a long time in an opened container. Most developers, silver salt solutions and ferric salts keep better in dark—e.g., amber or brown—bottles which prevent the contents from being decomposed by actinic light rays.

Developer stock solutions stay fresh longer if they can be kept out of contact with the air. There are several ways of doing this:

One method is to float a film of paraffin on the top of the solution and to draw off the developer through a glass tube that dips under the surface. In this case fresh solution must be added before the oil falls to the level of the open end of the tube.

Another method is to drop glass marbles into the bottle as the solution becomes used up so as to bring the level up to the neck of the bottle. This reduces the surface of the liquid in contact with the air in the bottle and so retards oxidation.

With modern plastic bottles it is easy to squeeze the bottle itself to reduce the air space to a minimum. The bottle cap must of course fit tightly. Plastic bottles are less recommended for long-term storage owing to their porosity.

EXHIBITIONS AND SALONS. Photographic salons and exhibitions are either confined to members of a particular society, or are exhibitions which are open to all photographers anywhere. Practically all active photographic societies run an annual exhibition of their own members' work either on the society's own premises or in some local hall. The bigger societies which promote open and international exhibitions always arrange for an adequate display in local halls or art galleries. Such exhibitions to be successful and gain general acceptance must comply with rules laid down by The Royal Photographic Society in this country or by The Photographic Society of America in the United States. The conditions are becoming fairly well standardized throughout the world so that entrants may be assured of a fair deal.

Briefly, it is stipulated that there must be no restricted classes, that the accepted entries shall be properly shown in suitable premises and that conditions should allow for the proper display of at least 150 prints. Exhibitors are thus assured that their prints will be suitably displayed if accepted.

The generally accepted conditions are:

(1) Entries shall be limited to not more than four prints from any individual (an exception to this is the London Salon which allows six prints).

(2) All pictures shall be submitted to the judges or selectors.

(3) The exhibition is not limited to special types of photographer—e.g., to men or women professionals, miniature photographers, or any other arbitrary classification less than the entire photographic body.

(4) The promoters must publish and furnish a complete catalogue of prints accepted and hung.

Entry forms must be provided and as names and addresses of successful entrants are nearly always published in the exhibition catalogue, regular exhibitors are in the habit of receiving

CC-0. Agamnigam Digital Preservation Foundation (Chennai) and eGangotri

entrance forms from exhibitions all over the world. Would-be exhibitors who have not yet been so successful can find from the photographic press regular notes about all the important exhibitions at home and abroad.

Mounts. Most exhibitions limit the size of the mount to 16 × 20 ins., although a few such as the London Salon will accept up to 20 × 25 ins. 16 × 20 ins. is a good standard size and it is the size that should be adopted by entrants who wish to send their pictures to a number of different exhibitions. This size will always be accepted and much smaller mounts are not generally desired. If, for example, the pictures are displayed under glass it is necessary that the mount should fit the size of the glass used and this is generally made to cover the 16 × 20 ins. mounts.

Entrance Fees. It is customary to ask for an entrance fee—e.g., five shillings or a dollar—to cover the expenses of running the exhibition. One of the few exceptions to this practice is the Annual Exhibition of The Royal Photographic Society for which no entrance fee is required. People sometimes object that exhibitions should not charge an entry fee as they are asking for work from exhibitors, but on the other hand very few exhibitions charge an admission fee and there is the cost of the hire of the hall or gallery to pay, the cost of printing the catalogue, and many other incidental expenses. In any event, few societies are able to make an exhibition pay, and practically all are prepared to lose money and look upon the cost as good publicity for the society.

Organization. Organizing a photographic exhibition is no easy task. Once it has been decided when it is to be held and the necessary hall has been booked, entrance forms have to be sent out all over the world, and the necessary publicity notices have to be sent to the photographic press. Arrangements must also be made for the reception of the parcels, their unpacking, checking, and counter-checking with the entrance forms. The importance of adequate space for this work is often overlooked, for it is by no means unusual for a society to receive several hundred parcels of 16 × 20 ins. prints and anything from 1,000 to 1,500 individual pictures. As all of these pictures will have to be returned in the original wrapping, a proper system has to be worked out for unwrapping, marking the packing paper to correspond with the numberings on the print, checking the entrance forms, taking out the postal orders, cheques and other forms of entry fee, and arranging the pictures for the judges or selectors. It is most important for all the wrappings to be safely stored for the month or two which will elapse between receipt and re-dispatch.

Arrangements have to be made to notify suitable selectors in advance of the judging date and provide accommodation for them. In most cases a panel of selectors is chosen, consisting of three or perhaps five members so as to make a majority vote possible. On the day of judging, facilities must be provided for placing the prints in proper lighting in front of the judges and for recording their decisions. Once the selection has been made, the forms have to be marked and the pictures transported to the place where they are to be hung. Arranging the pictures on the walls is a highly skilled task which should be entrusted to someone with experience because the appearance of an exhibition can be made or marred by the way in which the pictures are displayed. Pictures which are likely to conflict with one another must be kept well apart and a general harmonious arrangement of all the prints aimed at. Once the order of pictures has been decided upon they must be numbered and a catalogue prepared. The catalogue must then be printed and dispatched to successful entrants at once. It is customary to have the exhibition opened by some well-known person and, if the society is to benefit from the publicity of this exhibition, necessary arrangements must be made to have it reported in the local newspapers and the national photographic press. P.W.H.

EXPEDITION PHOTOGRAPHY. Expeditions, no matter what their nature or purpose, must always be recorded comprehensively by a competent photographer. All the requirements of the organizers of the venture must be met—in still and cine, and in black and white and colour. The photographer must further bear in mind possible uses for picture and film material by the popular press, for television, and for lectures. Photographs frequently prove excellent fund-raisers, to help finance either the venture they depict, or future expeditions.

It is essential to gain a clear idea, well before the expedition leaves, of the precise nature of the photographic records which are required, and the particular purposes to which they will eventually be put. Adequate documentation and illustration is an essential part of the responsibility of the explorer to posterity.

A small venture can afford to leave its photography in the hands of one who is primarily there as a geologist, naturalist, or doctor, and who regards the taking of pictures as just another job, but the high standards demanded today make the inclusion of an expert cameraman essential in any expedition of importance. It may even be found necessary to have one man for stills work, and another for movie work.

It is prudent to obtain a clear understanding (preferably in writing) before departing, of the copyright position; normally copyright of all photographs taken on the expedition should belong to the expedition as a whole, and would be vested in the leader, or the financial sponsor at home. Agreement should be reached at an

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

early stage on the procedure to be adopted. If, for instance, the doctor wanted to use his own unofficial pictures to illustrate a lecture, or a book on his experiences; preliminary discussion and formal decision on such matters before departure can avoid much hard feeling later.

EQUIPMENT

The time and trouble spent on selecting, designing and testing the equipment to be taken will be amply repaid on location; repairs or modifications then are likely to prove difficult or unreliable, or even impossible. Early discussion with the manufacturers on the best type of equipment for the conditions likely to be encountered is strongly recommended.

Complete re-lubrication of all camera moving parts might be necessary if sub-zero temperatures are to be met and this is a task for the expert. Lack of this precaution may cause shutters to become sluggish, or not to work at all, when very cold; lens mounts and aperture adjusting rings may become impossible to turn, because of the great increase in viscosity of ordinary lubricants below zero.

Modifications in camera design may also be found advisable. Some controls, for instance, cannot be manipulated with any ease by thickly-gloved hands, and this difficulty must be overcome.

If work is to be done at extreme temperatures, whether high or low, attention should be paid to dimensional clearances in the film path, or the film movement mechanism. The coefficients of expansion of dissimilar materials are unlikely to be identical, and adequate clearances at + 20° C. may prove entirely inadequate at − 40° C. This is the type of problem which the well-informed manufacturer would be able to handle effectively. Special machining of the interior may well prove essential, if the equipment is to work reliably.

Even if the equipment is of the highest standard, it is still essential to test it under conditions as near as possible to those likely to be encountered.

Practical experience with cameras which have been cooled to sub-zero temperatures should be gained if an expedition to the Arctic is proposed—and several hours must be allowed for the cooling procedure, as it takes a surprisingly long time for the interior of a camera to get really cold.

Even more important is the testing of any apparatus to be used under water. Pressures well in excess of the maximum likely to be met should be imposed upon all equipment, as a substantial safety margin is advisable. This precaution should be observed with all equipment to be taken under water, and not merely with the photographic apparatus.

Cameras and other instruments to be used in caves must be protected from moisture. This applies particularly to any electrical gear.

Expedition conditions are frequently such that the photographer works under considerable physical and mental strain. At extreme temperature human reactions tend to be slow, and at high altitudes the relative lack of oxygen impedes clarity of thought. When submerged, the photographer has so many other things to think about that there is a grave risk of his attention becoming distracted from his main purpose. For these reasons it is important that the camera controls should be simple to use. As much as possible of the operation should become mechanical, leaving little for the photographer to do, except to select the subject and press the button. To this end, much thought in simplifying the controls of the instrument before departure will be amply rewarded.

SENSITIZED MATERIAL

Careful consideration should be given as early as possible to the types of sensitive material to be employed, and again the experienced guidance of the manufacturers should be enlisted.

At low temperatures, the sensitivity of the emulsion decreases, and its colour balance may alter; provision for dealing with this first alteration is simple, if the extent is known. The shift of colour balance is more difficult to predict, and a series of practical trials may be necessary; the appropriate correcting filter for any given circumstances may then be determined.

At high altitudes, the ultra-violet content of the light tends to be much higher than near sea level, and adequate U.V. filtration is important.

Another difficulty to be expected at low temperatures is the tendency of the film base to stiffen, and become brittle, and even to snap if sharply stressed. This factor should be remembered when selecting equipment; cameras which employ sharp bends in the film track will almost certainly lead to trouble, and modifications in design may become necessary.

In hot climates changes in sensitivity, and in colour balance, are again to be expected, but a much greater problem arises through the inherent instability of the emulsion under hot and humid conditions. At above 40°C., emulsion stocks can become useless in a few weeks; they produce the faults which are normally associated with out-of-date films, i.e., high fog-level, low emulsion speed, low contrast, and low maximum density and, with colour films, a pronounced colour shift. The obvious precautions are to keep the films in their original sealed tropical wrappings as long as possible, to store them after use in a dry atmosphere (by the use of silica gel, in a closed container) and to maintain them, both before and after exposure, at as low a temperature as can be achieved.

This advice to keep emulsions cool may seem vain in an arid desert at 50° C., but much may

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

be accomplished by the use of wide-mouthed vacuum jars, or even by burying the stocks in the sand, as it is very much cooler two feet below the surface. The location must, of course, be carefully marked.

If adequate cooling and prompt processing cannot be assured, then it would be unwise to attempt to make any use of infra-red material, as this has notoriously poor keeping qualities under these conditions.

The relative instability of the latent image in any emulsion kept at high temperatures must never be over-looked. Since apparent under-exposure is the most obvious result of this instability, the experimentally-minded photographer, if faced with the utter impracticability of cool storage and prompt processing, might care to investigate the effects of deliberate over-exposure. It would, however, require luck to gain complete satisfaction in this way.

PROCESSING

The precautions to be taken after exposure are also of great importance, and plans should be made, if possible, to process films with the minimum of delay, and to subject them to minimal temperatures during the inevitable storage period. The provision of a temporary darkroom at base should be considered, before the expedition departs. It is highly desirable to make arrangements to fly exposed colour films home, for the more carefully controlled treatment they demand. However, a technique has been worked out, for certain stocks, which enables the first development to be performed in the field, so that the effects of subsequent storage become relatively unimportant.

Provision should be made if possible, to process an occasional test-film on the site, to enable both the condition of the material and also the technical quality of the photography to be assessed at regular intervals. If films cannot be processed on location, and all material is sent home for development, then the expedition photographer should be sent regular reports on the condition and technical quality of his work. D.H.O.J.

EXPIRY DATE. Date stamped on cartons of roll films and packings of 35 mm. film to indicate the date by which the material should be developed. Generally this is 2–2½ years from the date of coating for black and white materials, and about 1½ years for colour materials; the manufacturer's guarantee of the film does not normally extend beyond the expiry date, although the material can generally be used for considerably longer.

EXPLODED VIEWS. Photographs of machines or similar constructions dismantled into their parts and laid out so as to correspond as closely as possible to the way in which they are assembled.

Exploded views of articles consisting of an assembly of smaller parts have a special function in engineering. They show clearly how separate components are assembled, and indicate details of internal construction that may not be obvious in a complete unit. In advertising, exploded views help to emphasize important selling points about the way the article is made up and are of special value for instructional and educational use in the form of illustrations in literature or as lantern slides or film strips.

Drawings (line or wash) do not always carry the conviction of a genuine photograph; but on the other hand, special care must be taken when using a camera in order to avoid such faults as distortion, heavy and featureless shadows and wrong relative size of components. A number of small errors of this sort may collectively render an otherwise good photograph useless as a functional illustration.

It is as well for the photographer to possess some technical knowledge of the type of subject to be exploded, and special skill is called for in arranging and lighting the groups to make the picture tell the right story.

General Arrangements. The final print must show the exploded parts and nothing else. A plain background must be used and the components arranged on it in the order of assembly to avoid an horizontal line produced by the join of a vertical background with the table-top. The main item should be placed in such a position in relation to the camera that the other parts can be added with as little overlapping as possible.

Side elevations (sometimes used in drawings) are generally avoided because of the way in which the perspective of successive parts increases with their distance from the centre. As an example, a washer directly in front of the camera and edge-on appears as a straight line; when additional (and similar) washers are added on each side, the images progressively become more circular. In practice the centre washer can be turned slightly (technically known as "cheating") to show the third dimension, and the more distant washers can be turned in the opposite direction to lessen the effect.

It is generally necessary to suspend small parts by fine threads (that can be touched out afterwards) or use small pieces of clay or plasticine to fix them in position on the background. Sufficient separation between parts must be left to show their individual identity; but by varying the distance between certain groups it is possible to indicate the order of assembly. Sufficient perspective should be given to show the third dimension without

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

causing one part to hide another, and the assembly as a whole should not recede in too steep general perspective or it may falsely indicate a reduction in size for the more distant parts. It is common practice to include all small screws or bolts, not as if they were suspended in mid-air, but arranged in groups near their functional position, so that their use is easily inferred.

Lighting. One of the commonest failings in photographs of mechanical components is the introduction of conflicting shadows by the use of complicated lighting arrangements. Forward shadows (back lighting) are sometimes effective, but in general, hard lighting must be avoided and special care taken to ensure that no shadow links one part with another. As a rule, soft frontal lighting is safest as it is often impossible to cancel out shadows from one side by balancing the light from the other. In a few cases it may be necessary to light the group by reflected light from a large sheet of white paper, or by turning the lamps on to a white ceiling. When dealing with polished metal surfaces it may be helpful to photograph the subject within a tent constructed from tracing paper or other translucent material, otherwise any polished surface that does not reflect light will appear black. Shadowless lighting can be achieved by placing the parts on a sheet of translucent material which is illuminated indirectly from below—i.e., by reflected light from a white sheet of paper below this surface.

Camera. For this work a camera with a complete range of camera movements is essential. Skill in the use of camera movements can be effective in overcoming difficulties in focus and perspective. Longer-than-normal focus lenses are most helpful up to a point, and tend to flatten perspective, which, in most cases, is an advantage. Normal and shorter-than-normal (wide angle) lenses increase perspective and are notoriously unsatisfactory when used close to small subjects arranged on the table-top.

One other cause of failure is sometimes produced by vibration. In general it will be necessary to employ a small lens stop, which in turn will mean longer exposures. Even the smallest amount of subject movement can spoil such an assembly, and it pays to take a great deal of trouble to ensure that both camera and subject are rigidly supported so that relative movement is impossible. B.A.

EXPLOSIONS. In the study of explosions, photography can show what happens at the centre: the initiation point and speed of detonation; the velocity of the gaseous and solid products. Photography can also measure the blast: the speed, shape and behaviour of shock waves; their propagation from variously shaped charges; and the effects of their collision or concentration.

Of the precautions necessary to protect operators and equipment, the most obvious is to get as far away as possible and use telephoto lenses.

This may be many miles for nuclear explosions, a remotely-controlled camera, being mounted in a tower, protected from blast, and photographing through a telescope. Distances can be shorter for conventional explosives, while for close work the explosions are contained within blast walls or pits and observed through periscope systems. Extreme close-ups are possible with miniature charges, housed in metal or reinforced wooden boxes with replaceable armoured-glass windows.

The photographs are generally taken by multiple exposures in still or lenticular plate cameras or with high speed framing cameras taking up to several million frames per second. Rates of expansion may be measured with streak cameras.

Most explosions produce light, which can be used for illumination but is often a disadvantage since the flash obscures the subject. It is usual therefore to underexpose for the explosive flash by using small apertures and high shutter speeds, then to flood the subject with light from other sources, so that the non-luminous gases, solids and shock waves are properly recorded.

These sources must obviously be powerful and may comprise electronic flash, argon bombs, spark gaps and rare gas discharge tubes.

A single flash, used with a high-speed framing camera, must have a flat uniform output so that all the frames are evenly exposed. In open flash methods, where flash duration determines exposure time, this may be under 0·01 microseconds, several flashes, controlled by delay timers, producing multiple exposures.

Smoke obscuring an explosion can be penetrated by a high-intensity X-ray flash, beamed through the subject from a point source, to make a shadowgraph on a film opposite. Here the flash heads are protected behind heavy wooden "windows" transparent to X-rays, while instead of a camera, only an X-ray film holder is needed, designed to blow away without damage.

Several other methods produce shadowgraphs, and often involve simplified schlieren techniques to record blast waves. They may be made by incident light from behind the explosion or by reflected light against a screen. Blast can also be observed by the apparent distortion of straight lines or posts, due to the differential refractive index of air at the wave front.

Where camera shutters are called for, electro-optical devices such as the Kerr cell provide the microsecond exposures required. They are not completely opaque, so are usually supplemented by rapid-action mechanical shutters; one

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

opening immediately before the explosion, another closing afterwards.

Such systems require precise programming and synchronization, both with the explosion and the flash. A typical sequence is for the shutter to initiate the explosion which then triggers the flash.

Alternatively, the explosion may trigger the shutter, and the shutter the flash. Photocells, explosive switches, shutter synchronizing contacts and electronic timers provide triggering impulses. P.B.M.

EXPOSURE

Exposure in the scientific sense is the product of the intensity of light and the time during which the light acts. In terms of practical photography it means the particular combination of lens aperture and shutter speed that must be chosen to give a good negative.

The aim of the photographer is almost always to achieve a satisfactory print or transparency by giving the least possible camera exposure. This may be for three reasons: to get a print of the best possible quality by keeping the actual value of the exposure low; to keep the duration of exposure short, to arrest movement; and, by keeping the lens aperture small, to give the greatest possible depth of field. The last reason does not always apply: there are times when a large aperture is used deliberately to reduce the depth of field.

In some instances the brightness range of a subject is too wide to be recorded by the photographic process. This applies in particular to colour photography: in a scene with a wide range of tones only a limited group will be reproduced in correct colours—hence the recommendation of choosing "flat" subjects for colour photographs. Where it is impossible to do anything to reduce the brightness range of such a subject by suitable lighting, the photographer must make up his mind which group of tones he wants to come out in true colours and then expose for that group.

An under-exposed photograph lacks detail in the areas corresponding to the shadows; over-exposure causes the highlights to become flat and "burnt out".

In black-and-white photography by the negative-positive process, there is a range of exposures that will give satisfactory prints, reproducing quite faithfully the tones of the original scene. This range is a measure of the latitude of the emulsion. But the art of correct exposure is to give the least possible exposure that will show the required amount of detail in the shadow portions of the final print. Resolution will then be at a maximum, and grain at a minimum. Hence the old saying "expose for the shadows and the rest will take care of itself".

Reversal—and in particular colour reversal—materials have much less latitude than those used for negative-positive work. For direct colour transparencies there is only one correct exposure, and deviations one stop higher or lower give only just acceptable results.

Blackening Effect. Apart from the above term, the scientific definition of exposure denotes the total amount of light falling on the unit area of the photographic material, i.e., the product of the intensity of the light and the time during which it acts. The important thing is to know how much exposure produces how much blackening after development.

In general the blackening of the image increases with increasing exposure, but it is not always constant for the same total exposure. When sensitive materials are given the same total exposure throughout a range of varying values of time and light intensity, it is found that for each material there is one combination of time and intensity that produces most blackening. A reduction in intensity and corresponding increase in time, or an increase in intensity and a corresponding reduction in

EXPOSURE AND TONE SCALE. An average subject will, with correct exposure, record every tone value by a corresponding reversed density on the negative. Under-exposure records only the highlights, and all shadow tones remain clear without detail. Over-exposure records the shadows, but all brighter tones become uniform black.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

time, will decrease the blackening. In other words changing the intensity and time from their optimum value, lowers the photographic sensitivity. This effect is called the reciprocity failure.

The blackening also changes if the exposure is given intermittently. This happens because an intermittent exposure works in the same way as a long exposure at a lower intensity. If the same exposure is given continuously to one piece of material and intermittently to another, the total time taken by the exposure is greater for the intermittent case and the average intensity is decreased. The result is similar to an exposure given at lower intensity and as a rule causes the sensitivity to decrease. The effect is important in the design of instruments for sensitometry.

Exposing for Shadows. The light image that falls on the sensitive material in the camera consists of a series of patches of different degrees of brilliance. All these patches receive the same time of exposure, but because the intensity of the light on them varies, they are reproduced as areas of different densities on processing. These densities are faint for the shadow portions and heavy for the highlights.

When camera exposures are correct, the shadows in all scenes are reproduced as areas of similar low densities. On the characteristic curve which shows how the negative density changes with increasing sensitometric exposure—i.e., the product of intensity and time—this means that the shadow portion of a negative always falls near the toe. This is where the slope of the curve is still sufficient to reproduce shadow detail by an appreciable range of densities in the negative. Correct camera exposure for the shadows means that the shadows are tied to a small range of low densities.

Exposing for Highlights. It is not always convenient or desirable to expose for the shadows and many people prefer to expose for the highlights or the intermediate tones. Exposing for the highlights means that a highlight is always reproduced at a constant (relatively high) density, whatever the subject. Similarly, exposing for intermediate tones means that the mid-tones come out on all negatives as a reasonably constant medium density.

These methods of exposure are particularly useful for reversal materials where the positive transparency is to be projected on to a screen. Here it is not as important to reproduce shadow detail as it is to show, say, face tones at roughly equal brightness on the screen in every picture.

Exposing for highlights or intermediate tones rather than for the shadows is also useful where the tone range is too wide to be taken care of by the print. In such cases it pays to sacrifice detail in the shadows rather than in the medium tones and highlights.

Before the photographer can choose between exposing for the shadows or the highlights, he must be able to estimate or measure the tone range of his subject. What follows is concerned with the method of using various devices to determine the correct exposure for any particular set of conditions.

Estimating Exposure. With modern photographic black-and-white materials, a standard exposure of 1/50 second at *f* 11 will give a reasonable negative for a surprisingly large number of amateur snapshots. This is because most of such photographs are taken in bright sunny weather and the subject is generally in the nature of a group of people in the open or something involving streets and buildings.

With average subjects of this sort, any variation in lighting is usually well within the latitude of the film, so one standard exposure will serve on most occasions. A few simple and easy-to-remember rules cover the occasions when the standard exposure is not suitable. Thus: very early or very late in the day, multiply the standard exposure by ten; in shade, multiply it by two to four; in bright open places like the beach, or on mountains, divide it by two to four.

Rough and ready rules of this sort cannot guarantee first class results every time, but when they are combined with a little experience they will nearly always give a negative that can be made to yield a satisfactory print.

Indirect Methods. Under this heading come calculators, tables, and all methods of fixing the exposure without direct reference to the actual subject in front of the camera. It is possible to fix the exposure in this way because the strength of the light at any particular place and time is roughly the same every year.

So it is possible to give a reasonably accurate figure for exposure once the following facts are known: the geographical latitude, the time of the day and year, the weather, the type of subject, and the speed of the sensitive material.

The geographical latitude determines the height of the sun, and thus the amount of light that reaches the subject. This figure can be stated accurately for any particular place.

The time of the day and year also determines the height of the sun. The time of year is usually given simply as the month. The time of day should be given in solar time and not in British Summer Time or any similar artificial time. Local times may vary from solar time by as much as three quarters of an hour since it is generally inconvenient for local time to vary from one part of a country to another. The errors introduced into the estimation of exposure by using the wrong time of day are small around midday but may become quite large when the sun is low.

The weather is the remaining factor that decides the strength of the light falling on the subject. This cannot be measured accurately and depends upon how the individual photographer interprets a number of conditions.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The brightest possible weather condition is a clear sun with white clouds. The clouds help to reflect light to the earth's surface, thus lightening the shadows. Rather less light comes from sun in a clear blue sky which gives very strong shadows.

Shadows are one of the most important helps in estimating weather conditions. They are deepest for the "Clear sun", slightly weaker for the "Sun and white clouds" which do not obscure the sunlight, definitely watery for "Hazy sun" and absent for both "Dull" and "Very dull" weather conditions. The last two classifications probably cause more trouble than the others because they cover a much greater range of possible light values than any of the others. Only experience can teach which one to apply.

These factors—latitude, time and weather—govern the light that falls on the subject.

The subject, according to its reflecting powers, governs the amount of light reflected into the camera to form the image. So the subject is classified according to its light-reflecting properties.

There are two current ways of classifying the subject. In one the subject is classified by its character: "open sea", "distant landscape", "landscape with light foreground", "landscape with medium foreground", "close up subjects", etc. In the other, the subject is classified by its tone: light, medium, or dark, sometimes its distance from the camera, and often the direction of the light falling on it. The existence of these two subject scales is responsible for much of the difficulty that people experience in using exposure tables, charts and calculators.

The user of an exposure chart or guide must remember that the same subject at different distances from the camera and under different conditions may require different exposures. Thus, a figure in silhouette against the sky some distance away is interesting for its shape, and not for its shadow detail, for the simple reason that the eye looking at the original scene is not capable of resolving the detail. But the same figure closer to the camera will call for a longer exposure because in this case there will be visible shadow detail to record.

There is another reason why a distant figure requires less exposure. A certain amount of light is always scattered by haze in the air between the distant subject and the camera. This scattered light tends to lighten the shadows and to destroy the detail in them, both to the human eye and the photographic material.

The direction of the light may also have a considerable effect on the final exposure. Exposure against the light must always be heavier than exposure with the light, unless the light source itself forms part of the against-the-light scene, e.g., in a sunset. When photographing directly with the light, the shadows are invisible both to the eye and the camera. This is a high-key photograph for which exposure is always relatively small.

By contrast, when photographing directly against light, all the shadows are directed to the eye and the camera, so shadow detail is extremely important and exposure must be relatively heavy. There is one exception to this rule: when photographing a silhouette effect, shadow detail is not only unimportant, it is undesirable, so the subject needs only a short exposure.

Direct Methods. The above methods arrive at the exposure without actually measuring the strength of the light falling on or reflected from the subject. But provided that certain precautions are observed actual measurement of the light gives more accurate results. There are several ways of measuring the light that exposes the sensitized material in the camera:

(1) Actinometers measure the strength by the time the light takes to darken a test patch of sensitized material to a standard depth.

(2) Extinction meters relate the strength of the light to the faintest image that the eye can see through a neutral density wedge.

(3) Integrating exposure meters measure the cumulative effect of the light on a photo-electric cell over a period.

(4) Photo-electric meters indicate the light strength in terms of the electrical signal generated by a photo-electric cell directed either at the subject from the camera, or at the light source from the subject.

(5) Photometers measure the relative brilliance of a typical area of the subject.

The use of these instruments to determine exposure varies according to their different principles and is discussed under the individual headings.

Calibration. There are many reasons why it pays to go to some trouble to calibrate an exposure meter. The first is that no two meters, even meters of the same make and model, can be expected to respond in exactly the same way. The same can be said with even more truth of the camera shutters which eventually decide the exposure. Finally, individual photographers have their own ideas of what is a well-exposed negative.

The meter should be used to find the exposure for a series of photographs of widely different subjects. Each subject should be photographed at one quarter, one half, twice and four times the indicated exposure.

Inspection of the developed film will show at once which value of the indicated exposure gives the desired type of negative. If the exposure required is consistently greater or less than the indicated reading, the easiest way of making the correction is to adopt a correspondingly higher or lower speed figure for the negative material. This applies in particular when using automatic cameras.

The meter must be calibrated separately for

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

EXPOSURE METER SYSTEMS. Left: *Measurement of strength of light by an actinometer. This establishes the time taken by a piece of sensitive paper to darken under the influence of light so that it matches a predetermined depth of tone. Correct exposure is derived from this time.* Centre: *Measurement of average brightness of light reflected from subject by means of an extinction meter (observation of detail through a scale of numbers of increasing density), or by a photo-electric meter.* Right: *Measurement of brightness of individual subject areas by matching against them an illuminated area in a photometer. Adjustment of lamp illuminating the comparison area gives value for brightness. (The lamp is calibrated periodically to provide a zero point.)*

any of the other methods of use—incident light, substitution (i.e., taking readings on near-by objects of the same tone as a more distant subject), etc. It must also be re-calibrated if the photographer makes any change in the developer or development technique.

The speed figure finally adopted should allow for the fact that an under-exposed negative is no good, whereas an over-exposed negative will at least give an acceptable print. So, for general work, it is wise to adopt a speed figure of one half of that which would, according to the calibration, give the exact exposure. This recommendation is good for black-and-white negative and positive materials and even for colour where separate negatives and positives are used. It does not apply to reversal materials and normal colour materials, where only the exact exposure is admissible.

Minimum Correct Exposure. For best possible image quality the minimum exact exposure is desirable even with black-and-white negative materials. This applies especially to miniature and ultra-miniature camera films on the one hand, and to materials of very high sensitivity on the other. While under-exposure obviously leads to loss of image detail in the shadows, over-exposure beyond the minimum level necessary (in other words making use of the exposure latitude) tends to coarsen the image grain, and decrease definition. It does so by bringing out more of the image in the depth of the emulsion and so increasing the visible effect of light scatter and irradiation.

For these reasons the above-mentioned safety factor (adopting one-half of the speed figure that would give the exact exposure when setting the film speed on the exposure meter) is not in the interest of image quality, but only of convenience.

Such a safety factor is equally undesirable with ultra-speed negative materials. In this case the same image deteriorating factors already mentioned play their part to an enhanced degree. Further, the purpose of an ultra-speed film is to permit the shortest possible exposures in unfavourable light conditions. Hence the use of a speed reducing safety factor is a waste of versatility.

At one time standards of film speed rating and of exposure meter calibration between them more or less automatically led to exposures with such a safety factor. Methods of film speed measurement were internationally revised from 1960 onwards, and current standard film speed ratings, when used with a normally calibrated exposure meter, yield virtually the minimum correct exposure for the material.

Development Technique. The type of developer and the technique of development influence the effective speed of the sensitized material—

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

and hence the exposure it needs. Some fine grain developers, for instance, greatly reduce the effective speed and may require four times the normal exposure to be given. The exposure must be made with this fact in mind.

Exposure (Light) Values. The result of using any exposure calculator or meter is to obtain a number which indicates the camera exposure necessary to get a satisfactory picture with a material of given speed. This number has been called the exposure value.

The exposure recommendation embodied in an exposure value reading can be translated into a range of lens apertures and shutter settings—e.g., 1/25 second at *f*8, 1/50 second at *f*5·6, or 1/100 second at *f*4. These combinations all represent the same exposure value or photographic exposure.

It is decidedly desirable to be able to vary either shutter speeds or lens apertures in such a manner that the exposure value is automatically kept constant. This is realized in a number of modern shutters. Here a special exposure-value control is set to the number which has been obtained either from an exposure table or a suitably calibrated meter. This control is coupled to the diaphragm. Once it has been set, any change in the shutter speed setting will automatically alter the diaphragm so that the total amount of light passed on pressing the shutter release remains constant. Thus the shutter cannot be re-set without altering the diaphragm opening, but the diaphragm can be changed independently of the shutter, thus providing the same degree of flexibility as with the normal types of shutter.

This cross-coupling feature of the exposure value system survives in cameras with built-in coupled exposure meters. As, however, the process of reading off and transferring an exposure value is eliminated, the exposure value scale becomes unnecessary. The meter setting control simultaneously sets also a correct aperture-speed combination; alternative combinations are then selected as before by the cross-coupled controls.

Choice of Speed-Stop Combination. All systems of exposure measurement give exposure recommendations in the form of a series of shutter speeds and lens apertures. The photographer must make the final decision about which particular combination of aperture and shutter speed he will use: a small aperture and a slow speed, or a large aperture and a fast speed? There is no meter that will give the answer. Provided that the effective exposure remains constant, any one of a number of speed-stop combinations can be chosen.

There are two conflicting requirements to be reconciled. One is the need to stop down the lens to gain the utmost depth of field; the other is the need to keep the exposure time short so that a moving object or camera shake will not blur the picture.

When a camera is focused for a certain distance, objects in a zone extending both in front of and behind the plane on which the camera is focused also appear reasonably sharp. This zone is the depth of field.

The depth of field is governed, among other things, by the size of the lens aperture; the smaller the aperture, the greater the depth of field. So in the final speed-stop combination, the stop must be small enough to give a depth of field that will include all the objects that must appear sharp in the finished photograph.

But if the object is moving during exposure, the image on the film will also be moving all the time the shutter is open. This means that no matter how quickly the shutter opens and closes the image is bound to be blurred. But the faster the shutter speed, the smaller the blur will be. So in deciding on the speed-stop combination, the speed must be fast enough to reduce the blur to such a small amount that it will not show in the final print. The permissible amount of blur is decided by the diameter of the circle of confusion.

Finally, if the camera is to be held in the hand, there is the need to guard against camera shake. For the majority of photographers and cameras, this means that to get a really sharp picture, the shutter speed should be 1/50 second or even shorter. Some people can hold a camera steady for as much as 1/5 second, but this ability is rare.

The stop and speed finally chosen must reconcile the above—not always compatible—

CHOICE OF SPEED-STOP COMBINATION. A given exposure corresponds to a range of speed-stop combinations. A rapidly moving subject (symbolized by multiple arrow) needs a fast shutter speed and therefore a large aperture, which in turn covers a narrow zone of sharpness (shown by height of shaded area). A subject of great depth needs a small aperture and therefore a slow speed, which will not, however, arrest fast movement. Choice of best settings may need a compromise.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

requirements either by a compromise or by deliberately ignoring one of the factors.

Certain simple cameras with coupled meter relieve the photographer of this worry by providing only one aperture-speed combination for each exposure setting—usually a compromise which would be used in the majority of cases. Cameras with such a so-called programmed shutter may not even have aperture or speed scales at all, and make picture taking technique simpler—at the expense of some versatility in special conditions, where exceptional depth of field or high speed may be needed.

EXPOSURE AUTOMATION

The photographic process depends on the action of a specific amount of light on a sensitive material. This quantity of light can be measured by various means. So it is not surprising that designers of photo equipment have tried at various times to make light measuring devices directly regulate the mechanisms and adjustments that control the exposure in a camera or other photographic system. Exposure automation is the term applied to set-ups which do this purely by the action of light and without direct interference by the operator. (The latter must however make appropriate calibrating adjustments to set the system for specific operating conditions such as the speed of the sensitive material employed.)

This characteristic distinguishes automatic exposure control systems from semi-automatic ones, where the exposure is set by the physical adjustment of a measuring device to take an exposure reading.

Systems of exposure automation may in a camera control the aperture or shutter speed setting or the shutter operation itself. In an enlarger or other printing equipment an automatic system is usually employed to control the printing light or in some cases a mechanical shutter.

STILL CAMERAS

Aperture Control. The simplest form of exposure automation in a still camera controls the size of the lens diaphragm by the current from an exposure meter. Where in a normal meter the current flows through the coil of a measuring instrument, it is here led through one or a pair of minute coils associated with feather-light metal leaves. According to the current flowing through the coil, these leaves are pulled across each other to a greater or lesser extent. The leaves themselves are so designed that their movement results in a larger or smaller aperture through which the light reaches the lens. As more light falls on the meter cell, the leaves move in such a way that the opening formed by them becomes smaller; with less light the opening becomes larger.

Exposure control systems of this kind have been fitted in inexpensive still cameras as well as cine cameras. They allow only a limited amount of calibration adjustment for film speeds (see below) and usually are associated with a single speed shutter.

Servo—Control Setting Systems. A more complicated but also more versatile approach is to use a mechanical scanning system to determine the position of the indicating needle of an exposure meter built into the camera. This scanning mechanism is then linked to a shutter or aperture setting drive.

In practice this is how such a system works. When the photographer begins to press the release button of the camera, a stepped cam moves down over the exposure meter needle. The end position of this cam depends on the position of the meter needle, and hence on the light falling on the photo cell. Further pressure on the release button then frees a spring which drives the aperture setting ring until it is stopped by the scanning cam. The point at which the aperture setting ring—controlling the iris diaphragm—stops depends in turn on the position of the scanning cam and hence directly on the amount of light which reached the meter cell. Alternatively, the camera release button may directly drive the aperture setting ring until the scanning mechanism stops it.

A number of variations of design exist. Thus

SIMPLE ELECTRIC EYE STILL CAMERA SYSTEM: A, film speed setting control; places a mask B in front of meter cell to cut down light for slower films. C, aperture plates worked by meter gear D, to increase or decrease light going through lens. E, meter coil. F, meter cell inside finder. G, thermistor and resistor circuit to compensate for temperature variations.

AUTOMATIC SELF-POWERED SHUTTER SETTING. 1. Before release. 2. During releasing, before the exposure. Pressing the release actuates a spring which makes the scanning segment of the exposure meter lock the meter needle in its position. The movement of the control cams for shutter speeds and apertures is arrested in a position corresponding to the needle position. A, cam follower for shutter speed settings. B, shutter speed control cam. C, cam follower for aperture settings. D, aperture cam. E, arresting segment of programming ring. F, release button. G, scanning segment of exposure meter. H, meter needle. J, spring of scanning segment. K, lever linkage engaging programming ring.

the servo drive may be linked to both the aperture and the shutter speed adjustment (as in programmed shutters), or it may adjust the shutter speed when the aperture setting range has reached its limit (or vice versa). More elaborate, but less reliable, servo systems have also been proposed. In one the exposure meter was linked to a thin plate that partially covered a perforated plate and so obstructed the flow of air from a kind of dashpot to a greater or lesser extent. This air flow was then used to regulate the shutter setting.

Yet another system uses a small electric motor to drive a setting pointer to a position where it lines up with the meter needle. The same motor then also drives the aperture and shutter speed adjusting rings to set a correct exposure time. Motorized servo systems are however more common in cine cameras.

Calibration Adjustments. Like a straightforward exposure meter, automatic control systems need adjustment for films of different speed. In the simplest designs this can be done by putting neutral density filters in front of the meter cell or by obscuring part of the cell surface and so adjusting the effective sensitivity.

In servo systems involving a coupling between the exposure meter and the exposure setting mechanism, the calibration adjustment is built into the coupling.

In such systems it is frequently possible to pre-select a shutter speed and let the scanning mechanism adjust only the lens aperture. In the simplest case the shutter speed selection itself also acts as a film speed setting: the camera works with slow shutter speeds for the slowest films and with the highest shutter speeds for fast films. Where there is a shutter speed adjustment on top of the film speed setting, this merely involves having a wider adjustment range to accommodate the two.

Exposure Signals. Since a camera with auto-

AUTOMATIC SHUTTER DRIVEN EXPOSURE SETTING. Pressing the release drives the shutter cam, controlling the aperture and speed settings, until the scanning cam of the meter is arrested by the meter needle. 1. Before release. 2. During releasing, immediately before the exposure. A, cam follower for shutter speed settings. B, shutter speed setting cam. C, cam follower for aperture settings. D, aperture cam. E, gear sector and gearing. F, release button. G, needle scanning segment. H, exposure meter needle.

SCHEME OF DIRECT EXPOSURE CONTROL OF SHUTTER. On pressing the release a suitable device (e.g. a release magnet) opens the shutter. It also initiates light measurement via a photo cell. When an appropriate amount of light has reached the cell, a further control element closes the shutter. A, release. B, release magnet. C, impulse generator or other initiating system for light measurement. D, photo cell. E, closing mechanism of shutter. F, measuring unit of photo cell—for instance a switch comparing the impulse direct from the generator C with a second impulse weakened by the photo resistor cell.

matic exposure control sets itself according to the prevailing light, some indication is necessary for the user to show whether the light conditions are adequate for a correct exposure. This is usually done by coloured signals visible in the camera viewfinder. When a red signal appears, or persists on taking the first pressure on the release button, the light is insufficient for the exposure range provided and no correct exposure is possible. If the signal is green or turns green on pressing the button, the prevailing light conditions are suitable for a correct exposure.

On cameras permitting a pre-selection of shutter speeds, a red signal can be turned green by choosing a suitable slower shutter speed. In some cases the signal is given by a pointer visible in the camera finder, which moves from a green to a red sector (or vice versa), and may also indicate the actual lens aperture selected by the automatic mechanism. Alternatively, a green and red aperture scale may move past a fixed index mark.

Yet another method of providing an exposure signal is the blocking of the release button when the light is unsuitable for a correct exposure.

In conditions where the automatic system is incapable of setting a right exposure, either flash or time exposures are usually possible by disengaging the automatic control. With some cameras such disengagement permits the setting of any non-automatic exposure combination.

Direct Shutter Control. While the systems so far described rely on light measurement with an instrument which is coupled with the aperture and/or shutter controls, a more direct approach to shutter operation is also possible. Here the current from the photo cell is used to regulate the closing of the shutter, after the latter has opened for the exposure. The exposure commences by the opening of the shutter, which then remains open until an electric circuit releases the closing blade or blades or triggers the closing phase. This involves no light measuring instrument as such, but an electric storage system such as a capacitor or an electronic detector.

On opening the shutter for the exposure a current starts to flow through a photo-resistor cell to charge up the storage circuit. When the latter is charged, an overspill current (in some cases running through a transistor system) triggers the closing phase. If the light intensity falling on the photo-resistor cell is great, the charging period—and hence the interval before the closing phase is triggered—is comparatively short. In poor light the resistance of the photo-resistor increases and the current takes longer to charge up the electronic storage system, thus leading to a long exposure time. In practice, control systems of this nature can cover exposure times from 1/1000 second (or even shorter) to several minutes in a continuous range.

If the measuring cell is situated so that it receives the light through the camera lens, the exposure time automatically allows for the lens aperture in use.

The charging time can also be varied by appropriate adjustment of the electric circuit; this provides for different film speed settings. Where the photo-resistor cell does not receive the light coming through the lens, a switching adjustment has to be linked with the aperture control so as to select different response sensitivities at different aperture settings.

In view of the cumulative action of such an exposure system, it can respond to very low lighting levels. Hence the usual stop/go signals are rarely necessary. Instead a special signal may be provided to warn the user that the exposure time will be long enough to necessitate the use of a tripod.

ELECTRIC EYE SYSTEM OF CINE CAMERA. The light reaching the meter cell powers a moving coil galvanometer connected to a diaphragm plate which increases or decreases the effective lens aperture. A pointer forming part of the plate may be visible in the viewfinder, and indicate the actual aperture selected by the system. A, cadmium sulphide cell. B, iris diaphragm (controlling light reaching cell, used for film speed setting). C, pointer. D, camera lens. E, finder system. F, film. G, galvanometer. H, mercury battery.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Since the light reflected from the subject may change during, for instance, a panning shot the electric eye system should monitor and adjust the camera exposure setting continuously. This is perfectly straightforward with direct aperture control systems and to a more limited extent with motor-controlled servo systems.

Direct Aperture Control. Most of the simpler automatic or "electric eye" cameras utilize a straightforward aperture control system relying on the movement of light-weight blades with special cut-out slots. These blades are moved in front of the lens (or between the lens elements) by a coil or coils energized by the current passing through the meter cell. This system is therefore similar to that described for simple still cameras. There is usually a limited adjustment for different film speeds, achieved by partially obstructing the meter cell to a greater or lesser extent. Sometimes a range of framing speeds of the cine camera may also be accommodated in this way. Where a cadmium sulphide photo resistor cell is used, the adjustments may also involve the electric circuit.

Where the photo cell receives the light coming through the lens (usually by a beam splitter somewhere in the optical path or a reflecting shutter), linking the cell to the aperture control provides an automation system which also corrects its own errors. As the light falling on the photo cell depends partly on the light passed through the lens aperture, any tolerances or inaccuracies in the aperture calibration and in the mechanical linkages directly affects the meter cell as well. This will then readjust the aperture accordingly.

Motorized Servo Systems. In a number of cine cameras the current from the exposure meter circuit is balanced against a reference current in a bridge circuit. Any unbalance actuates a servo motor which drives the aperture adjustment to increase or decrease the lens opening until the point of balance is regained. Adjustment of the lens opening in this way may modify the resistance of the balancing circuit (and so allow for the greater or lesser amount of light falling on the photo cell). Or the light may reach the photo cell through the lens aperture, so that the motorized adjustment of the latter again automatically provides the point of balance—and hence correct exposure. The servo motor is switched on just before the camera starts running, and remains switched on during filming so as to follow all changes in light intensity.

PRINTING AND ENLARGING

Amateur Enlarging. Normal enlarging procedures use comparatively long exposure times (several seconds upwards) so that photo multiplier cell circuits become the most convenient means of controlling the exposure itself. In most systems a photo multiplier cell starts registering the light the moment the enlarger is switched on for the exposure. When sufficient light—reflected from the enlarging paper, going through the paper or diverted from the light beam going through the lens—has reached the cell, an associated relay automatically switches off the enlarger illumination. The associated electronic circuits have to be adjusted for the speed of the enlarging paper, and its surface reflection or transmission characteristics—according to whether the light is registered by reflection from the paper surface or through the paper base. The meter cells, however, automatically allow for the magnification and the lens opening of the enlarger. Where the light is measured in the enlarger beam (for example via a beam splitter) the magnification must be set in addition.

Commercial Printers. Printers and enlargers

used in photo-finishing laboratories largely utilize automatic exposure control systems of similar type. Since in commercial printing it is the output speed that matters, the photo cell system may be linked to the circuit that adjusts the printing light intensity rather than the duration for which it is switched on. In electronic printers using a flying spot scanner the measuring photo cell may control the intensity of the electron beam and so yield different printing exposures, according to the density of the negative, during a given exposure time.

Intensity control of the printing light is also used in continuous motion picture printers for producing positive prints from the negative film. Here the films run through the printer at a uniform rate, so variations of exposure time are impossible.

EXPOSURE CALCULATOR. Device which simply puts all the information contained in an exposure table into a more convenient form. It generally takes the shape of a slide rule with logarithmic numbers plotted in the form of scales, either along straight slides or circular discs. The most common calculators are really not pure calculators at all, but a combination of tables and a slide rule in straight or circular form.

Book: *Focal Exposure Chart*, by W. D. Emanuel (London).

EXPOSURE COUNTER. Mechanical feature on miniature and some roll-film cameras to indicate how many frames of a load of film have been exposed.

See also: *Film transport; Miniature camera.*

EXPOSURE DATA. Information printed as a caption beneath a published photograph, in photographic magazines and journals, giving details of the shutter speed, aperture, etc., used when the photograph was taken. Often based on recollection or reconstruction.

EXPOSURE METER

Instrument which measures light intensity and indicates this in terms of exposure settings for a camera. The light may be registered and measured in a variety of ways, such as the visible darkening of a piece of sensitized paper; comparison with the brightness of a standard light source; and by the effect on a photo-electric cell. Exposure meters using the latter system are most widely used and are also known as photo-electric meters.

The photo-electric exposure meter is designed around a so-called barrier layer or a photo-resistor cell. The former is a small metallic looking disc which generates an electric current when light falls on it. The photo resistor cell changes its resistance to a current flowing through it when light falls on the cell. In either case the current increases with the light intensity and is registered by a micro-ammeter. The reading of the latter is then a measure of the light intensity, and thus indicates the exposure required under given conditions.

Photo-electric exposure meters consist of a cell and meter unit, and an arrangement which converts the meter reading into an exposure recommendation based on the speed of the photographic material. Various methods are used to convert the meter reading into exposure settings for the camera, ranging from directly calibrated scales on which the pointer of the micro-ammeter shows actual exposure settings, to systems of mechanically lining up the meter needle with a setting index or marker. There the mechanical movement required also adjusts a scale showing exposure settings or adjusts the exposure settings of the camera itself.

DESIGN

The design of photo-electric meters varies from one make to another. Although all employing the same principle, meters differ in methods of use, particularly in translating the needle reading into terms of shutter speed, aperture and film speed.

Calculators. The original and simplest device for converting the meter reading into an exposure recommendation consists of two circular concentric scales, the outer marked in the whole range of shutter speeds and the inner in the whole range of lens apertures. The inner scale is normally fixed, but it can be unlocked and set in accordance with the speed figure of the sensitive material. The outer scale can be rotated. It carries an index mark on its edge that registers against a scale of light values marked on the face of the instrument.

Before a reading is taken, the outer scale is set to the speed figure for the sensitive material and locked in position. The meter is then used to take a reading and the pointer on the inner scale is turned to the light value indicated. The two scales are now in their correct relation to each other to give a complete range of related shutter speeds and lens apertures, any one of which will give the correct exposure. Whether the photographer chooses, say, 1/1000 second at *f*2, 1/30 second at *f*11, or any intermediate combination, will depend upon the subject conditions.

Setting Markers. Most current meter types have an auxiliary needle which is set to the indication of the meter. This act of setting automatically

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PHOTO-ELECTRIC EXPOSURE METER. The meter consists essentially of three units: the photo-electric cell, a micro-ammeter, and some kind of calculator. Top: *The photo-electric cell generates a current when light falls on it.* A, *very thin transparent layer of gold.* B, *contact ring.* C, *selenium layer.* D, *iron disc.* Centre: *The micro-ammeter measures the current produced by the cell.* E, *coil.* F, *magnet.* G, *scale.* H, *pointer.* Bottom: *The calculator converts the scale readings into exposure values.* I, *scale readings.* J, *film speeds.* K, *apertures.* L, *shutter speeds. Some meters have much more simplified calculators or are direct reading once a suitable scale has been selected for the film speed used.*

adjusts the calculator, allowing the correct exposure to be read off the calculator scale which has been adjusted for the speed of the material in use.

In another method, the meter needle is brought to the same point on the scale each time by a diaphragm, variable flap, or similar device which alters the amount of light reaching the photo-electric cell. Both methods are favoured with meters which are incorporated into cameras, since the act of setting adjusts the lens aperture and/or shutter speed of the camera at the same time. Some meters introduce variable electric resistances to bring the needle of the meter to the fixed reference point. More sensitive meters than those incorporating barrier-layer types of cell are those based on photo-resistors; these are substances, the electric resistance of which drops with increasing light flux falling upon them. The meter consists of the photoresistor, a small battery and a micro-ammeter, and its sensitivity may be of the order of 1,000 times higher than that of the barrier-layer type.

Reflected Light Meters. The commonest type of photo-electric meter measures the total amount of light which comes from the scene to be photographed. While it is the brightness of the shadows which determines correct photographic exposure in most scenes, the proportion of light to dark is fairly constant and the total amount of light reflected from the scene gives a reasonably accurate indication of exposure. At the same time, the reading needs to be interpreted according to the nature of the subject.

Since the reflected light meter is meant to measure the amount of light coming from the scene to be photographed, it must not receive light from areas outside the scene. It is usual to define an "angle of acceptance" which is the angle of the cone of light received by the meter.

Incident Light Meters. An alternative type of meter measures the light incident on a scene instead of that reflected from it. The principle of operation of such incident light meters is effectively that of measuring the brightest spot on a scene, this bright spot consisting of a piece of white translucent opal material—the receptor—which is arranged in front of the photo-electric cell. Such a meter is therefore used by holding it so that it receives the same light which reaches the subject.

The receptor has two functions; first, to take in all the light falling on those parts of the subject that face the camera, and second to present this light as a uniform bright surface to the meter cell. Incident light meters therefore do not rely on a limited acceptance angle; in fact the greater the acceptance angle the better.

The ideal receptor for an incident light meter is a hemispherical or conical translucent body placed in front of the cell. This covers the light reaching the subject over an angle of about 180°. Flat diffusing reflectors placed in front of the photo cell are almost, but not quite, as efficient. The light absorption of the diffusing receptor is usually so adjusted that the incident light meter yields the same exposure reading with an average subject as a normal reflected light meters, these being designed without its diffusing attachment). Apart from the receptor, the construction of the incident light meter is identical with that of the reflected light meter.

Built-in Meters. Many modern cameras have an exposure meter built into the body, and often coupled with the exposure settings. Built-in meters are usually highly compact versions of normal separate meters; cadmium sulphide cell systems permit particularly compact design.

Meters built into the camera are usually reflected light meters the meter being designed to take in the same angle of view as the lens and to be used from the camera position. This

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

makes for convenience in handling: the meter is always at hand and ready to use, and cannot be left behind. On the other hand the versatility of use is reduced; it is less convenient to move the camera about to take close-up or other special readings, and a built-in meter in a camera becomes particularly inconvenient for incident light measurement. Often no incident light diffuser is in fact supplied with such a meter.

The orthodox design of a built-in meter places the meter cell either around the lens (in fixed lens cameras), near the viewfinder window, or in some other convenient position on the camera front. Meters in this way measure the light reflected from the subject. Various attempts have also been made to measure on the one hand the light coming through the lens, and on the other the brightness of the image formed on the film or—in reflex cameras—on the viewing screen. Through-the-lens exposure measurement has the advantage, especially with interchangeable lens cameras, that the meter cell receives light from exactly the same subject field as is taken in by the lens. The acceptance angle of the meter is thus modified accordingly when a lens of different focal length is used.

Designs along these lines have used (a) a swing-away meter cell behind the lens (which moves out of the way immediately before the exposure), (b) meter elements built into the mirror of a reflex camera, (c) meter cells to which some of the light going through the lens was diverted by a beam splitter or other reflecting systems (popular in cine cameras), and (d) meter cells placed in the plane of the viewing screen or in some other position in the viewfinder system of a reflex camera. One difficulty with the last-named approach is that the meter should normally measure the light reaching the whole image area. A small meter cell in the centre of the focusing screen or other part of the viewing system can only measure a small portion of the subject. The meter cell then acts like a photometer and the exposure settings must be arrived at by appropriate spot readings.

ZERO SETTING CADMIUM SULPHIDE METER. The cadmium sulphide cell changes its electric resistance according to the amount of light falling on it and so controls a galvanometer in the circuit. In a zero setting system the light is kept constant by an iris diaphragm or similar device. A, battery of the meter circuit. B, galvanometer with meter needle lined up opposite a setting index. C, shutter speed scale. D, aperture scale (usually linked with the iris diaphragm H). E, film speed settings. The functions of the controls C and D may be directly linked to aperture shutter speed settings in the camera. F, switch (to prevent drain on the battery when not needed). G, cadmium sulphide cell.

NEEDLE MATCHING SYSTEM. The measuring instrument and the calculator are mechanically separate. The calculator is linked to a second needle or setting marker which is lined up with the meter needle. A, meter needle. B, coil. C, photo cell. D, setting marker. E, gearing. F, aperture ring. G, shutter speed ring. The setting marker may be geared to the aperture and shutter speed adjustments on the camera itself. The setting marker and meter needle appear in a common window.

If the exposure meter is behind the lens, the light reaching the meter automatically also allows for the lens aperture. Similarly, filters placed in front of the lens hold back light also from the meter cell (though the meter is not necessarily affected in the same way as the film by the filter).

Reflex cameras that keep the lens aperture fully open during viewing and focusing require a separate allowance for, or coupling with, the aperture adjustment.

Automatic Exposure Control. In the majority of built-in camera meters the setting control of the meter is mechanically coupled with the exposure settings (aperture and speed) of the camera. The operation of taking an exposure reading therefore directly sets the exposure as well. Such coupled meters are often advertised as automatic, though they still need a manual operation of lining up the meter needle with a fixed or movable pointer. They are more correctly described as semi-automatic.

In fully automatic exposure systems the meter mechanism is directly linked to the lens aperture (or shutter speed setting), adjusting the latter, directly or indirectly, according to the light falling on the photo cell.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The simplest mechanism uses two slotted feather-weight aperture discs geared to the meter coil. Movement of the slots relative to each other enlarges or reduces the effective lens aperture. In other systems the meter mechanism controls the movement of a mechanical stop or the meter needle is scanned by a mechanical device. The lens is then stopped down to the appropriate point by a spring-loaded pre-selector iris on pressing the shutter release. The pre-selector system may also work the shutter speed adjustment instead. Some cameras also employ miniature servo motors for the same purpose.

CHARACTERISTICS

Some of the performance characteristics of exposure meters have been standardized by appropriate standards of the British Standards Institution (B.S. No. 1383:1947) and of the American Standards Association (PH2.12–1957). These cover acceptance angles, sensitivity and colour sensitivity.

Acceptance Angle. The angle of acceptance decides the amount of light reaching a meter. It therefore also influences the apparent sensitivity of the meter, and has at times been made a misleading selling point. The above-mentioned standards specify the measurement of the acceptance angle. In practice the meter should not have an angle very much greater than the angle of view of the standard camera lens.

While it matters comparatively little with a subject of uniform brightness distribution (such as an open view) whether the meter takes in a very wide or a narrow view, a wide acceptance angle can cause the meter to give misleading readings under a variety of subject conditions. These include scenes where strong light sources or strong reflections appear just outside the field of view and may thus influence the meter reading. With a wide acceptance angle it is also more difficult to take reliable close-up readings.

Limiting Devices. Various devices are used to limit the acceptance angle. The simplest method is to arrange for the cell to be situated at the bottom of a "well". A single well must be deep to be effective, but the depth can be decreased by using many small wells, subdividing the whole area of the cell.

Another method is to arrange a lens in front of the cell to focus an image of the scene on the cell surface. In this way a rather larger amount of light reaches the cell than by the method of using a simple well; and the meter can be made much slimmer. Many meters use a multi-cellular lens which looks rather like an enlarged version of an insect eye.

Sensitivity and Measuring Range. Response sensitivity of exposure meters has been standardized by the British Standard Specification No. 1383: 1947 which requires a minimum deflection of 2 mm. of the meter needle for a change of 2 : 1 in brightness.

ACCEPTANCE ANGLE. Top: The angle of acceptance of the meter is usually limited by a hood in front of the cell. The curves shown are plots of the amount of light reaching the cell from the various directions when the meter is pointed at a uniformly illuminated surface. A, shallow hood covering a wide angle. B, deep hood covering a narrow angle. C, shallow hood with lens. This can still cover a narrow angle but receives more light than the corresponding hood alone, and is more compact. Bottom: To measure the acceptance angle, bring the meter up to a suitable test chart until the needle deflection is constant when the cell covers a well defined area.

The actual sensitivity of the meter to light depends on the meter design and also on the measuring range provided. High-quality selenium cell meters may react to lighting levels as low as 0.1 foot candle. An inexpensive meter of this kind built into a camera may have its lowest response level up to ten times as high; on the other hand a cadmium sulphide photo resistor cell meter may be 50 to 100 times as sensitive as the best selenium cell instrument. The highest lighting level likely to be encountered in normal photography is between 1,000 and 2,000 foot candles, so that a high-class selenium cell meter would have to cover a lighting range of around 20,000 : 1, and a cadmium sulphide cell of about 2,000,000 : 1.

Covering such range provides certain difficulties in obtaining the readings. It is often physic-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ally impossible to accommodate a sufficiently detailed and hence adequately accurate scale of light values within the movement range of the meter needle. There are various ways out of this.

On exposure meters using a movable setting marker (needle matching system) the needle movement—and hence also the marker movement—can be kept non-linear and converted to a linear movement of a much larger associated scale by means of a suitable mechanical cam. In the middle of the scale, comparatively large needle movements thus correspond to fairly small exposure differences; at either end of the movement range fairly small needle movement corresponds to appreciable exposure changes.

Simple cameras with built-in meters often have a very much restricted measuring range, achieved by keeping down the sensitivity of the meter. Where for instance a camera with exposure automation yields 1/30 second at $f2{\cdot}8$ as its lowest exposure level, there is no point in having a meter reading lower lighting levels than this with the slowest film likely to be used. So there a meter with a measuring range of about 500 : 1 is quite adequate. This corresponds to about 10 exposure value intervals, which are easy enough to handle.

The commonest way of covering a big exposure range is by means of two measuring ranges. One is the low light range, going from the lowest response limit of the meter to a level about 200 times as high. This covers mainly indoor and artificial light subjects. At higher lighting levels the meter cell is covered by a baffle which lets through about 1 per cent of the light, thus cutting down the effective sensitivity of the meter by a factor of 100. This at the same time increases the exposure range 100-fold, leading to a total range of 20,000 : 1. With the baffle in front of the cell the meter is then used for measuring brilliant daylight scenes.

With cadmium sulphide cell systems either a baffle or an electrical resistance can be used to cut down the meter sensitivity.

The exposure scale of the meter then carries two series of aperture (or shutter speed) figures, one for use with the baffle and the other without.

Some meters also take a booster cell to increase the sensitivity in very poor light.

Spectral Sensitivity. Photo-electric cells have about the same spectral sensitivity as the human eye. They have the same peak in the yellow-green, but are more sensitive to blue and red than the human eye. Meters vary considerably in their spectral sensitivity, particularly in their sensitivity to blue, and the American Standard Specification No. PH52.12–1957 dealing with meters allows quite wide limits for this.

The colour sensitivity of the cell is quite unlike that of any photographic material, even when colour filters are used to correct the colour sensitivity of the material. Thus, when using the meter on highly coloured scenes, it is possible for exposure recommendations to be misleading. This applies particularly to photographs of sea and sky scenes of the intense blue that sometimes occurs in southern countries. Under normal conditions, however, the discrepancies between the colour sensitivities of the cell and the photographic material are not important since the colour of the average scene is fairly constant.

SPECTRAL SENSITIVITY. The curves for photo-electric meters (solid) are not always the same as for the eye (dotted). The upper and lower limits of sensitivity shown are those acceptable to the American Standards Association.

METHOD OF USE

The figure indicated by the meter is an indication of the strength of the light, and no more. Before it can be used for calculating an exposure, two other factors have to be taken into account: what sort of negative the photographer wants to produce—dense, medium, or thin—and how the meter is used—i.e., what fraction of the light coming from the subject is actually measured by the meter.

Adjustment for Type of Negative. No matter which of the various methods of use the photographer adopts, he aims at getting the type of negative that suits his particular style of work. This type of negative may be either denser or thinner than the negative that would result from following the exposure indicated by the meter. But the exposure must be increased to get a dense negative and decreased to get a thin one. So the photographer must correct his meter reading so that, if necessary, he will consistently under- or over-expose his negatives by the right amount to give him the negatives he likes. The easiest way to do this is to calibrate the meter and adopt a suitably revised speed for the sensitive material.

Adjustment for Method of Use. There are several different ways of using a photo-electric exposure meter; some depend on personal

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

USING AN EXPOSURE METER. 1, *Over-all reflected light readings taken from the camera position with the meter pointing at the subject.* 2. *The meter should point slightly downwards to exclude large sky areas.* 3. *If the light is fully behind the camera, the exposure indicated may be halved.* 4. *Against the light, the exposure indicated should be doubled.* 5. *If the shadows are important, the meter reading should cover them at close range.* 6. *For a highlight reading the meter receives the light from a white surface lit by the main light. The correct exposure is then about eight times the figure indicated.* 7. *In substitution readings the meter is pointed at a grey card or other object chosen to match the important part of the scene. The substitute object must also receive the same light as the actual subject.* 8. *For incident light readings the meter points towards the camera from the subject, and thus measures the light reaching the subject. The meter cell must be fitted with a suitable diffusing cone or screen.*

choice, others are dictated by special circumstances. Each method measures a different fraction of the light reflected from or falling on the subject, and for any given set of lighting conditions each will give a different reading. But in the end, they must all lead to the same exposure, so each method has its own factor by which the reading must be multiplied before it will give the right answer.

The conversion factors are only approximate. They will help the photographer who wishes to change temporarily from one method of use to another. But if he wishes to adopt the new method permanently, he should calibrate his meter afresh to arrive at the exact speed figure for his purpose.

Average Scene Brightness. The most common method is to measure the average brightness of the scene to be photographed. To do this the meter is pointed at the scene from the camera position, looking at the scene in the same direction as the camera. This method is sometimes described as measuring the light reflected from the scene. Used in this way, the meter is accurate enough for a surprisingly large number of subjects. So long as the direct rays of the sun are prevented from falling on the light-sensitive surface of the meter, the exposures given should be satisfactory for most general purposes, using the speed figure given by the maker of the film or plate. But this method does not give reliable readings when the picture includes the sky.

Tilting the Meter. In ordinary black-and-white photography, at least, it is common practice to expose for the shadows. But, using the above method of measuring the average scene brightness, two scenes with the same shadow brightness which included different amounts of sky would give two different exposure readings.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The one with the largest sky area would show the bigger reading and would get too short an exposure in consequence.

For this reason it has become standard practice to tilt the meter down at about thirty degrees to the vertical so that the sky has no part in the meter reading. It is easy to see when the sky has been excluded by watching the reading as the meter is tilted down. The reading will first decrease quite rapidly and then reach a steady value when further tilting makes no difference. This steady reading is the one to use.

Since excluding the sky reduces the meter reading, it is necessary to compensate for the change by adopting a new figure for the speed of the sensitive material. On an average type of subject, a speed figure double that used when pointing the meter straight at the subject will be satisfactory.

Close-up Method. If, instead of using the meter from the camera position and tilting it down, it is brought close to the important part of the subject, the sky is automatically cut out. This is a favourite method with many workers and so long as a preliminary set of calibrating exposures is run off, it gives consistently good results. It has the disadvantage that it takes no account of the effect of haze between the camera and subject. To allow for the brighter tone value of the haze, the exposure must be shorter by about half, or the normal speed figure for the material should be doubled.

Allowing for Tone Range. The speed figures supplied with the meter for normal use from the camera position are worked out for an average type of subject. If the tone range of the subject is especially wide, the shadows will be deeper and should therefore have a longer exposure than in normal subjects. But the highlights will be brighter, thus giving a higher meter reading and indicating an even shorter exposure. So that to put matters right, the subject should be given double the indicated exposure, or the normal speed figure for the sensitive material should be halved.

Similarly, if the subject has an unusually narrow range of tones, the indicated exposure should be halved, or the normal speed figure for the sensitive material should be doubled.

The above recommendations apply to negative materials. With a reversal film the highlights must remain correctly exposed even if the subject has a wide tone range and no doubling of the exposure is therefore desirable. If the tone range is unusually narrow, however, a correctly exposed reversal transparency will appear rather dull and dark because there are no bright highlights. In this case the indicated exposure should be doubled, or the normal speed figure for the sensitive material halved. In practice this applies especially to outdoor exposures on colour film in dull weather, mist, etc.

When the exposure is based on the shadow brightness, what happens to the highlights will depend on whether the tone range of the scene is narrow enough for the negative material to be able to cope with it.

Often the tone range will be too wide to be recorded by a single exposure, so that either the deepest shadows or the brightest highlights have to be sacrificed. So, for critical work, the meter must be used to measure the whole tone range. If it is too wide it may be possible to correct it by throwing additional light into the shadows with a reflector or a flash bulb.

The tone range is the ratio of highlight to shadow brightness. For an average subject it is of the order of 100 : 1. But light is scattered in the lens and dispersed into the shadow areas of the image on the sensitive surface. This compresses the tone range by an amount that depends on such things as the properties of the lens and the distribution of light and shade in the scene. A tone range of 100 : 1 in the scene is compressed under average conditions to about 30 : 1.

The tone range is measured by taking a reading first on a highlight in the scene, and then on some shadow detail. When doing this the angle of acceptance of the meter must be completely filled by the portion of the scene to be measured.

FILM SPEED FACTORS FOR METER METHODS

Measurement taken	*Multiply normal film speed rating by*
Average scene brightness	1
Meter tilted at 30 degrees	2
Close-up	2
Close-up for subjects of wide tone range	½
Close-up for subjects of narrow tone range	2
Shadow brightness	16
Artificial highlight	⅛

When shadow detail is an essential part of the picture, the shadow brightness can be measured direct by bringing the meter close up to a representative shadow part of the subject. The angle of view of the meter must be completely filled by the shadow portion. When the meter is used in this way it will give a very much smaller deflection than if it had been pointed from the camera position. So the speed figure for the sensitive material should be multiplied by 16 (or the exposure divided by 16 if the speed scale of the meter will not show such a large figure).

Artificial Highlights. All the methods of using a photo-electric meter described so far have been concerned with correct rendering of shadow detail without reference to what happens to the rest of the picture.

For subjects of wide tone range this may mean that the highlights are beyond the range of the material so that they will appear "burnt out", i.e., lacking in detail. An alternative method which guards against this failing is

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

to use the meter to measure the brightness of an artificial highlight. This may either be a highlight present in the scene itself, or one which is placed there in the form of, say, a white handkerchief.

The exposure given is based upon this highlight reading in such a way that in the photograph the density of the strongest highlight is always the same, no matter what the subject or its lighting. In other words, the strongest highlight is "tied" to the top of the characteristic curve just as in the shadow method the weakest shadow is "tied" to the toe of the curve.

If an ordinary photo-electric meter is used to measure the brightest highlight in this way, it will give a very high reading and recommend a very short exposure. The exposure recommended will, in fact, be about six times too short so the indicated time must be multiplied by six, or the normal speed figure divided by six, to get a correctly exposed negative. As in all other methods discussed, the exact multiplying factor can only be found by actual experiment.

Using Incident Light Meters. It is but a small step from measuring the brightness of an artificial highlight to incorporating it in the meter itself, as is done in incident light (or highlight) meters.

Incident light meters were originally designed to be pointed at the light, but many photographers now prefer to point the meter at the camera. A hemi-spherical receptor in this position is illuminated in much the same way, for example, as a human face. The exact shape of the receptor apparently does not matter much as long as it adds up evenly all the light falling on it. Some meters use cones or inverted cones, or even flat screens.

It is sometimes necessary—with artificial light in particular—to set up an incident light meter where the illumination on it is representative of that falling on the subject. As a rule, however, it is sufficiently accurate to take a meter reading from the camera position with the meter pointed towards the lens.

Exposure by incident light meter gives highlights of constant density. This is an advantage in any work, particularly for colour materials where faulty exposure not only produces faulty tones, but also upsets the colour balance. It is again an advantage in any work where the tones should appear much the same from one negative to the next, because the brilliance of the highlights (and especially of the skin tones in colour photography) establishes the general tone of the picture.

Duplex Method. Possibly the most critical way of using an incident light meter is the Duplex method. It involves two meter readings: one with the meter facing the camera, the other facing the strongest light falling on the subject. The camera exposure derived from these readings is the *f*-number which is half-way between the *f*-numbers corresponding to the two readings. In most instances an incident light meter in which the light collector is conical or hemispherical in shape will give an exposure recommendation which is the same as that given by the Duplex method.

Key Tone Method. The most popular types of photo-electric meter aim at correct exposures for the shadows, and highlight meters are only concerned with the highlights. But there is an intermediate method designed to give an exposure that will reproduce the medium tones at a constant density.

In this case, instead of pointing the meter at the subject, it is pointed at an artificial medium tone such as a piece of grey card. The reading obtained will of course depend on the reflection density of the card and must be calibrated separately for any particular tint.

This key tone method of measuring the amount of light from a grey card can be applied to any selected tone, darker or lighter than the medium grey. Some photographers carry about with them a series of grey cards from which they select one matching the brightness they are interested in.

They find it easy to stand at the camera position and pick out the card that comes nearest to the brilliance of the important part of the scene. Once they have decided which card to use they simply point the meter at it and take a reading. This saves them the trouble of walking over to the subject with the meter—a course that is not, in any case, always open where the subject is inaccessible.

Incident Light Method with Normal Meters. Sometimes the light is so weak that the normal meter does not give a reading when pointed at the subject in the usual way. When this happens the meter can be used as an incident light meter and pointed at the light instead of the subject.

The ordinary meter is not calibrated for use in this way, and no rigid rule can be laid down to suit every meter since not all meters respond in a similar fashion. In any case, the nature of the subject itself influences the final exposure.

But as a first rough guide the meter reading should be reduced 100 to 1,000 times. Even so, it will still be wise to give exposures of ¼ and 4 times, as well as the estimated exposure, to be certain of a good result.

Limitations of Built-in-Meters. Exposure meters built into a camera are more awkward to use for special reading methods (close-up, highlight, duplex, incident light) which involve taking a reading from a position away from the camera view point. With an electric-eye camera where the meter sets the exposure controls immediately before the exposure, readings other than straightforward reflected light readings of the actual subject become virtually impossible. The meter cell has to take in the actual view recorded on the film during the reading. Direct reflected light readings give

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

reasonably reliable exposures in about 90 per cent of all picture taking occasions. There are two ways of dealing with some of the remaining 10 per cent.

(1) Where the exposure has to be halved, doubled, etc. for subjects of unusual tone range, the film speed setting can be adjusted instead. Thus to halve the effective exposure the film speed setting on the meter is doubled (A.S.A. scale). But remember to reset the film speed adjustment to its normal rating again afterwards.

(2) Close-up readings and readings with the meter tilted slightly downwards can be made by depressing the release button slightly during the taking of the reading. That takes up the first pressure and locks the exposure selection mechanism. The release button must be kept partly depressed in this way while taking up the position for the actual picture, and then pressed through fully. This is fairly easy when the camera only has to be tilted slightly between the reading and the exposure; it becomes more awkward when movement of the camera from one position to another—with the release button partly depressed—is involved.

EXPOSURE TABLES

Tables listing all the factors which affect the exposure. These are: the weather; the subject; the time (of the day and the year) and the latitude, which determine the altitude of the sun; the altitude; the speed or sensitivity of the photographic material; the filter factor.

A figure is given to each. The user has to estimate the various conditions, and add up all the figures. The answer is a figure opposite to which the exposure can be read off in a table.

Alternatively, all this information may be conveniently contained on an exposure calculator, e.g., in the form of a slide rule.

The basic idea underlying the design of all exposure tables and similar devices is that the various factors listed are independent of one another and that any one can vary without affecting the rest. But this assumption is only approximate and for this reason alone the results are not as accurate as those obtained with meters that measure the actual light on the spot. Still, for most purposes the latitude of the photographic materials is enough to take care of any errors.

The main errors in the estimation of individual factors occur with weather conditions and subject brightness. While full sunshine is reasonably predictable in strength (except in industrial areas where smoke haze cuts out quite a lot of light), dull weather may vary widely according to the thickness of the cloud layer. Similarly, subjects in normal light are straightforward enough; scenes in the shade, especially under trees, etc., are rather undefinable in brightness (e.g., the trees may be nearly bare or full of leaves).

The following list shows by comparison what sort of accuracy can be expected from such methods of measuring exposure. It proves that quite satisfactory results can be obtained by the use of exposure tables or calculators.

Exposure tables, charts and calculators	45%
Extinction meters	87·8%
Photo-electric meters	97·3%

Standard Exposure Tables. The tables which follow were at one time the basis of a British Standard (No. 935:1948), and are typical of the conditions that have to be taken into account.

To use the tables, add together the numbers corresponding to the appropriate conditions in tables 1 and 2. Then subtract from the total the number from table 3 corresponding to the speed of the film or plate used. The resulting number will enable appropriate values of exposure time and lens aperture to be obtained from Table 4, as shown in the example given below.

Example.—A photograph of a near-by, unshaded subject is to be taken at 4 p.m. B.S.T. in September, at a latitude of 50° N., the sun being obscured by slight haze. The material being used has a speed of 40 A.S.A.:

from Table 1e—lat. 50° N.: Sept., 3 p.m. G.M.T. (4 p.m. B.S.T.)	1
from Table 2—hazy sun; near-by, unshaded subject	58
Total	59
For 40 A.S.A. (see Table 3) subtract ..	27
Final number	32

Suppose that the photograph is to be taken at *f* 8. In Table 4, in the line corresponding to *f* 8, the number 32 does not occur; therefore take the nearest figure, which is 31, and the exposure time indicated is 1/30 second.

Care should be taken in using the figures for the light indices (tables 1a–1g) early and late in the day. The figures have been worked out for the middle of the respective months, and may not be reliable earlier or later in the month at the first or last hours of the day. The times used are local solar times, not official local time.

TABLE 2a. SCENE INDICES FOR BLACK AND WHITE NEGATIVE MATERIAL

Land and marine scenes

Scene	Distant	Semi-distant	Near-by			Close-up		
Shade condition			Un-Shaded	Light Shade	Heavy Shade	Un-Shaded	Light Shade	Heavy Shade
Clear sun	*49	*52	*55	58	61	*58	61	64
Hazy sun	*52	*55	*58	61	64	*61	64	67
Cloudy, bright...	55	58	61	64	67	64	67	70
Cloudy, dull	58	61	64	67	70	67	70	73

*Side lighting, add 3; back lighting, add 6.

Sky conditions.—Clear sun—scene illuminated by direct obscured sunlight, but light clouds may be present.

Hazy sun—the sun's light weakened by a blanket of haze, but the sun's disc still visible. Haze may weaken sunlight early or late in the day, even if the sky is clear overhead.

Cloudy, bright—the sun obscured by light cloud, but its approximate position discernible by a bright area in the sky.

Cloudy, dull—the sky nearly or completely filled with heavy cloud.

Shaded scenes.—Light shade—scene shielded from direct rays of sun but illuminated by about half of the open sky.

Heavy shade—scene shielded not only from sun, but from most of the sky (e.g., scenes in narrow streets).

Scene structure.—Scenes are classified in Table 2a according to distance, because subject distance provides a fair index of lowest scene brightness; as the subject distance increases, dark parts of the scene appear to merge with lighter areas, raising the lowest scene brightness.

Semi-distant objects, photographed with a long-focus lens to yield the effect of a close-up, should be treated as a close-up.

Reversal films do not relate exposure so directly to lowest scene brightness and the classification of distance is omitted from Table 2b. it may be noted, however, that the scene indices given in Table 2b for side and back lighting may be varied by 3; decreasing the index increases the dramatic light effect, increasing the index yields more detail in shadow areas.

TABLE 2b. SCENE INDICES FOR REVERSAL MATERIAL*

Shade condition	Front Light	Side Light	Back Light for Lighting Effect	Back Light for Shadow Detail	Light Shade	Heavy Shade
Clear sun	52	55	55	58	61	64
Hazy sun	55	57	57	59	—	—
Cloudy, bright	58	—	—	—	—	—
Cloudy, dull	61	—	—	—	—	—

*These indices are for average coloured subjects. For light coloured subjects, subtract 2 from the index; for dark coloured subjects, add 2 to the index.

TABLE 3. INDICES FOR FILM SPEED (TO BE SUBTRACTED)

Speed	ASA	10	12	16	20	25	32	40	50	64	80	100	125	160	200

EXPOSURE VALUE. Setting on certain shutters to give exposures as ranges of aperture-shutter speed combinations by a single setting. The setting in effect controls the actual light reaching the film, irrespective of the combination of aperture and shutter speed, as long as the exposure value setting remains the same. Exposure values are sometimes also referred to as light values.

Some exposure meters show their readings as exposure values; these may again be either arbitrary, or expressed in photometric units such as foot candles, which have to be transferred to a calculator disc.

Shutter Values. The exposure value scale on various modern shutters combines apertures and shutter speeds in a single exposure setting. The exposure values usually run from 2 to 18, and each exposure value represents a given amount of light passed through the lens. The higher the exposure value, the less the light passed through; or, from the point of view of setting exposures, the brighter the subject, the higher the exposure value that must be set.

This system reduces exposure to its simplest terms. All the photographer has to do is to find the exposure value for the prevailing conditions from a suitably calibrated meter or table, and set the shutter scale to the same value.

The scale of exposure values is so arranged

EXPOSURES AND EXPOSURE VALUES

Exposure Value	Shutter Speed (Seconds) at Aperture									
	f1·4	f2	f2·8	f4	f5·6	f8	f11	f16	f22	f32

EXPOSURE VALUES. A shutter scaled in light values has coupled aperture and speed settings. Bottom: for a given light value (e.g., 11) setting a fast speed automatically opens the aperture, or stopping down sets a slow speed, so as to keep the exposure constant. To change the exposure for different light conditions, simply alter the light value setting.

that each number is equivalent to half the exposure of the next lower number, and twice the exposure of the next higher number.

Any given exposure value covers a range of aperture shutter-speed combinations that yield the same exposure. For instance, the exposure value 13 gives a range of aperture/shutter-speed combinations—e.g., 1/500 second at *f* 4, 1/250 second at *f* 5·6, or 1/125 second at *f* 8, or 1/60 second at *f* 11—each of which gives the same amount of exposure. Similarly, an exposure value of 9 gives 1 second at *f* 22, ½ second at *f* 16, ¼ second at *f* 11, ⅛ second at *f* 8, etc.—again all the same thing in terms of the amount of light received by the film during the exposure.

The aperture and shutter speed settings on the shutter are coupled to the exposure value control; once an exposure value has been set, stopping down the aperture—e.g., to increase the depth of field—will automatically adjust the shutter to a correspondingly slower speed. Alternatively, setting the shutter to a fast speed (e.g., to cope with rapid subject movement) automatically opens up the diaphragm aperture.

The exposure therefore remains automatically constant for that exposure value if either shutter or diaphragm settings are altered.

The exposure value system can also be used for estimating exposures by rule-of-thumb. Thus an average subject in bright weather may need an exposure value setting of 12. For a brilliant subject it would be correct to advance the setting to 13; or if the sun goes in, to reduce it to 11 or 10, and so on.

In the same way filter factors can be considered as reducing the exposure value: for a factor of 2 the exposure value must be reduced by 1, for a factor of 3 by 1½, for a factor of 4 by 2, and so on.

Mathematical Equation. The exposure values E.V. of the exposure value scaled shutters are given by the equation:

$$2^{EV} = f^2 \times 1/t$$

where *f* is the aperture number, and *t* the exposure time in seconds. This can also be written as:

$$E.V. = \log_2 (f^2 \times 1/t)$$

or, more conveniently,

$$E.V. = 3{\cdot}322 \times \log(f^2 \times 1/t)$$

For instance with a shutter speed of ⅛ second ($1/t=8$) and aperture *f* 16 we get:

$$E.V. = 3{\cdot}322 \times \log(16^2 \times 8) = 3.322 \times 3{\cdot}311 = 11.$$

Therefore this combination corresponds to an exposure value of 11. A combination of ¼ second at *f* 22 would give $3{\cdot}322 \times \log (22^2 \times 4)$ which is $3{\cdot}322 \times 3{\cdot}288$, or 10·93, again approximately 11. Similarly, an equivalent combination of 1/250 second at *f* 2·8 gives an exposure value of $3{\cdot}322 \times \log (2{\cdot}8^2 \times 250) = 3{\cdot}322 \times 3{\cdot}292 = 10{\cdot}95$. All the speeds on the shutter are chosen so that they give exact or very near whole numbers when combined with the standard aperture numbers in the exposure value equation.

The exposure value scale is logarithmic, and can thus cover enormous exposure ranges with a comparatively limited series of numbers. A scale from 2 to 18 is sufficient for all normal photographic purposes, since it represents exposures from 1 second at *f* 2 to 1/500 second at *f* 22; in other words a range of over 1: 60,000.

A scale from about −16 to +22—less than 40 numbers—corresponding to a range of about 1: 250,000,000,000 would cover every conceivable exposure ever made, from an astronomical photograph taken on a long winter night of 18 hours to extreme speed shots of around 1/10,000,000 second.

Exposure values also fit into the Apex system, where the exposure value is the sum of similar single-digit unit values for the lens aperture and the shutter speed.

Cameras with coupled exposure meters work on the same system, including the cross-coupled aperture and speed settings, but have no exposure value scale. The latter becomes unnecessary where no transferring of readings is required from the meter to the shutter. L.A.M.

EXTENSION BELLOWS. Attachment for miniature and other rigid cameras with interchangeable lenses, providing a variable degree of lens extension for close-up and macro-photography. Usually—though not invariably—extension bellows are produced for specific camera models. Since the variable extension requires visual focusing, they are used with reflex cameras or in conjunction with reflex housings or attachments. The focusing range with extension bellows (using a lens of appropriate focal length) frequently covers distances from infinity down to same-size reproduction,

BELLOWS ATTACHMENT. This provides a variable extension for close-up work over a continuous range of distances. Bellows units are usually intended for miniature reflex or rangefinder miniatures in conjunction with a reflex housing. Mostly they are designed for specific camera models.

and often even larger. Various adaptor rings or fittings take different lens units.

The bellows attachment generally consists of a fixed rear member which attaches to the camera and a movable front unit which runs along two or more rails. In many cases the whole bellows attachment can also move forward and backward when mounted on a tripod. The movements are controlled by rack and pinion systems. For reference purposes one or more of the rails may carry numerical scales to enable a given camera setting to be repeated without lengthy experimenting.

See also: *Close-ups; Extension of camera; Extension tube.*

EXTENSION OF CAMERA. Strictly, the maximum distance to which the lens can be moved in front of the sensitive material. The term is also gene .lly applied to the extent of the focusing movement where this involves travel of the lens as a whole. Normally the amount of extension available allows the lens to be focused on objects down to about 3 feet.

With a double extension camera, a second sliding member on the baseboard allows the lens panel to be racked forward to give twice the normal lens-film separation. This permits objects to be photographed the same size.

With a triple extension camera, the baseboard is designed so that the lens panel can be racked forward to give about three times the normal separation, giving an enlarged image of objects.

A double extension is mostly essential for copying and for photographing objects measuring an inch or two. A triple extension is useful for really close-up photography—e.g., macro-photography, botanical photography and philatelic photography.

The extension can also be increased by the use of extension tubes. This method is only possible when the lens can be removed.

Long extension tubes—e.g., giving the equivalent of a double extension or more—are not used for the larger negative formats because they would be too bulky to be practical. For negative sizes greater than 2¼ × 2¼ ins. any considerable amount of extra extension is achieved by using an extension box. This is simply a box-shaped adaptor of the same size as the negative which either fits in between the plate holder and the plate back or between the lens and lens panel. Where the whole outfit must be reasonably portable, the extension box may be constructed in the form of a collapsible bellows. Extensions of this type are used on plate cameras when working with lenses of abnormally long focal length.

Extension and *f*-number. The marked value of the stop can be accepted as the actual effective aperture so long as the object is farther away than ten times the focal length of the lens. In practice this condition usually holds good within the focusing range provided by the normal single extension. But when a double or triple extension is used, the effective value of the aperture is appreciably reduced.

The practical rule for finding the new value of the *f*-number is to multiply the marked *f*-number by N/(N–1) where N is the number of times the object distance is greater than the focal length of the lens.

For example, if the object is one foot away when it is focused sharply by a 6 ins. lens (so that N = 2), then the effective aperture at any *f*-number is given by *f*-number × 2/(2–1)—i.e., *f*-number × 2. So that a stop marked *f* 4 would have to be regarded as *f* 8 when working out the exposure.

Extension and Magnification. The final purpose of devices for increasing the camera extension is to obtain a bigger image than the normal close limit of focusing will permit. If the scale on which the subject is to be reproduced is S (i.e., size of the object × S = size of image) then the amount of extension required is given by *f* × S.

For example, if the object is to be reproduced to a scale of half life size with a lens of 2 ins. focal length, the length of extension required would be E = 2 × ½ = 1 in.

Extension and Image Distance. When a lens of focal length f is required to work at a distance u from the subject, the amount d it

must be racked forward from the infinity mark is given by the equation:

$$d = \frac{f^2}{u - f}$$

For example, if a 10 cm. lens is to photograph an object 0·5 m. (50 cm.) away, the camera extension must be:

$$\frac{100}{50-10} = \frac{100}{40} = 2{\cdot}5 \text{ cm.}$$

Extension and Image Size. The size v of the image of an object of size u formed at a given extension d by a lens of focal length f is:

$$v = \frac{d\,u}{f}$$

For example, a 5 cm. lens focused on an object 1·5 cm. high with an extension of 2 cm. will produce an image

$$= \frac{2 \times 1{\cdot}5}{5} = 0{\cdot}6 \text{ cm. high.}$$

That is, two-fifths the original size. F.P.

See also: *Bellows; Close-ups; Extension tube; Macrophotography; Optical calculations; Reflex attachment; Technical camera.*

EXTENSION TUBE. Tube of specific length threaded to take the camera lens at one end and to screw into the mount at the other. Extension tubes are used to increase the working separation between the lens and the sensitive material to give a magnified image. They are used mainly for miniature and small cameras where they do not need to be of any great diameter. On larger cameras the extension is usually provided in the form of double or triple extension bellows.

Extension tubes are usually available in standard lengths: ½ in., 1 in., 2 ins., etc. They extend the focusing range in a number of fairly short zones. The focusing movement of the lens itself helps to bridge the gap between one fixed extension and the next.

EXTENSION TUBES. A set of tubes used with an interchangeable lens camera will yield a range of magnifications up to several times natural size. For greatest magnification use most tubes and shortest focus lens.

There is not much point in using short extension tubes with long focus lenses, as the focusing extension is often longer than the extension tube.

All the calculations for normal camera extension apply equally to extension tubes. The *f*-number correction is also the same.

The third table above provides a range of scales of reproduction for each lens-extension tube combination. The lower limit of the range applies to the lens when focused on infinity, the higher value to the lens focused on a close-up subject. The nearest focusing point of the lens alone is taken as about 3 feet (1 metre) for lenses up to 4½ ins. focal length, about 6 feet (2 metres) for 5–7 ins. lenses, and about 12 feet (4 metres) for 8–12 ins. lenses. The longer focus lenses are considered more as narrow angle lenses for miniature cameras, since the relatively narrow extension tubes would prevent them from covering the plate of a larger camera.

With the very long extension tubes the actual range of scales of reproduction obtainable by varying the focusing setting is comparatively limited. So only one value is given in the table above. L.A.M.

EXTINCTION METER. The early photographers used to estimate exposure by observing the image on the ground-glass screen of their cameras and shutting down the lens diaphragm until the details of the picture began to disappear. The knowledge of the sensitivity of their material and a simple conversion table allowed them to determine the exposure.

Visual Accommodation. The adaptation of the eye—i.e., its ability to see under a wide variation of illuminations—makes the extinction method unreliable. After prolonged observation under a dark cloth the eye will often see detail which was at first invisible. So to obtain reliable results with any extinction meter, the time of observation must be standardized. If this is done remarkably good results are obtained, even by different observers using the same meter.

Construction. Since the majority of cameras have no ground-glass screen, separate extinction meters have been developed. Many modern extinction meters use a wedge of graduated density with a series of figures behind it. This is mounted in a tube or a flat tablet through which the scene to be photographed is observed. The last figure which can still be seen is referred to a table, adjusted for the film speed, from which the exposure is read off directly.

Another type of extinction meter is simply a small camera in which a lens throws an image of the scene on to a small screen and in which the diaphragm is changed until the detail disappears. In another rather similar instrument the scene is used to illuminate a piece of opal glass against which a distinctive figure is placed. The diaphragm is altered until the figure becomes indistinct and the diaphragm reading gives the exposure directly from a table.

At one time, a diaphragm attachment was available for twin lens reflex cameras enabling the viewing screen of the camera to be used as an extinction meter.

Using Extinction Meters. The commonest source of error in using an extinction meter is to take too long over a reading. The remarkable powers of accommodation of the human eye will make it adjust itself to see faint figures in the meter that were invisible at the start. The extinction meter is probably the only instrument that gives more accurate results when it is used quickly and carelessly than when it is treated deliberately.

So with all extinction meters which are held close against the eye, the time of measurement must be standardized. This is not necessary with the type of meter which is held well away from the eye since in this case the general state of adaption of the eye is not altered. This type of meter is probably less reliable than the others and is normally available only in rather cheaply made forms.

Since the extinction meter makes use of a rather ill-defined property of the human eye, it is not surprising to find that different users

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

obtain different results with the same type of meter. So every user should calibrate his own meter to suit his personal characteristics. An extinction meter calibrated in this way can be a very reliable instrument.

Most extinction meters are designed to accept light from the whole of the scene. This fact may give rise to misleading readings. The meters should never be pointed directly at the sun or they will give meaningless readings. W.F.B.

EYE. Light-sensitive organ of vision. The human eye is a very highly developed organ; it is, in fact, part of the brain. In the embryo it begins as an outgrowth from the rudimentary brain, and later develops into the eye. While the eyes of animals and birds are more highly developed for special purposes, the human eye is probably the best for all-round performance.

Anatomy of the Eye. Like the camera, the eye has a lens, a shutter (the eyelid), a variable aperture stop or diaphragm (the pupil), and a light-sensitive surface (the retina).

The lens consists of a transparent elastic substance whose curvature—and consequently, focal length—are controlled by a ring of muscles round its edge. The eye is focused on objects at different distances by altering the focal length of the lens. The shape of the cornea however, contributes to the total focusing power. Due to the fact that the eye is filled with fluid, the internal and external focal lengths are different. For distant vision, the former is 22 mm. the latter, 17 mm. The diameter of the lens is about 10 mm. and the angle of view is between 150° and 170° depending on the orientation.

The lens itself produces considerable chromatic and other aberrations, but the interpretive mechanism of the brain normally allows for these defects. Spherical aberration, coma and astigmatism, although present, are reduced by the design of the eye, and the considerable field curvature is offset by the curvature of the retina.

VISUAL EXTINCTION METER. A, eyepiece. B, film speed scale on ring, also carrying shutter speeds. C, test object (cross, as shown below). D, diaphragm. E, diffusing screen. F, diaphragm adjusting ring carrying also aperture scale. In use the diaphragm is closed down until test object just disappears with meter pointed at subject; scales then indicate exposure settings.

THE HUMAN EYE. A, conjunctiva. B, retina. C, fovea centralis (yellow spot). D, ciliary muscles controlling the lens. E, iris. F, lens. G, cornea. H, blind spot, being the ending of the optic nerve; is virtually insensitive. I, choroid.

The pupil of the eye is a variable aperture situated in front of the lens and composed of a ring of muscle which lies in the coloured part of the eye. This muscle controls the size of the lens aperture and gives it a normal working range of about *f* 4 to *f* 8 (·15 in. to ·075 in. diameter, or 3·8 mm. to 1·9 mm.). The eye can adjust quickly between these limits, but, given time, it can cover a range from *f* 1·8 to *f* 12 (·33 in. to ·05 in. diameter, or 8·5 mm. to 1·25 mm.).

The size of the pupil is controlled by a reflex action from the brain; it automatically contracts in bright light and dilates in dull.

The Retina. The area of the inner wall of the eye ball is divided into a multitude of tiny light-sensitive cells which comprise the retina. These cells feed signals about the light falling on them to the brain via the optic nerve. There appear to be two different kinds of cell: firstly, the cones, which are used mainly in day vision and have high discrimination of colour and intensity level; and secondly the rods, which are mainly used in night vision, are much more sensitive but have no colour discrimination. There are about 7 million cones and about 120 million rods in the eye but they appear to be interconnected in large groups since there are only 800,000 nerve fibres in the optic nerve.

The rods and cones are not uniformly distributed over the area of the retina. A small area on the optic axis of the eye called the fovea is very rich in cones and has few if any rods present. Here the cones are spaced at intervals corresponding to about 700/mm. As we move out from this area, the cells become much less

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

densely packed and the rods quickly increase in proportion so that they far outnumber the cones. Thus the fovea has a high discrimination of both detail and colour for a wide range of the higher illumination levels (such as daylight), whereas the rest of the retina gives a blurred, mainly monochrome, picture and comes into its own only under night vision conditions.

The Mechanisms of the Retina. Over most of its range of sensitivity, the eye responds to the rate at which light reaches it rather than to amounts of light; in other words it deals with a continuous record rather than an instantaneous picture. Furthermore the retina and nervous system analyses the image received before transmitting the information to the brain in coded signals. There is therefore a closer analogy with a television system than with a photographic system.

If, however, a very short flash (less than $\frac{1}{5}$ second) of light enters the eye, the retina no longer responds to the rate at which light is arriving, but as if the amount of light in the flash had been spread uniformly over $\frac{1}{5}$ second. This is termed the persistence of vision. It implies that if a series of flashes arrives at a rate higher than about 5/second they will seem to merge together into a continuous illumination.

The signals sent to the brain by the retinal cells record only changes in light intensity. If the light is uniform very little information is transmitted. This method of analysis determines the way the eye is used. The head is moved to direct the optic axis towards the interesting part of the scene whose image then falls on the foveal region. The muscles holding the eye introduce a small continuous involuntary wobble so that the image is continually moved over the fovea. The resulting varying light intensities on the cones are a highly important part of normal vision. If the "wobbles" are stopped by an artificial optical device in front of the eye, normal vision soon disappears.

VARIATION OF DETAIL DISCRIMINATION ACROSS RETINA. The visual acuity (sensitivity to detail) is highest in day. vision when the cones are active (solid curve). The peak corresponds to the fovea and the gap to the so-called blind spot. For night vision when the rods are in use, acuity is very much reduced (dotted curve). It is in fact lowest in the fovea since this part of the retina contains hardly any rods.

RELATIVE LUMINOUS EFFICIENCY CURVES. The solid curve shows the luminous efficiency of the cones in the retina which operate for day vision; the dotted curve corresponds to the rods which operate for night vision.

Sensitivity. The mechanisms of vision operate over an enormous range of brightness (properly called luminance) from about 1,000,000 ft.-lamberts to 1/1,000,000 ft.-lambert—a range of 10^{12} : 1. The upper limit (10^6 ft.-lamberts) is set by the pain induced by intensely high lumniances. A pure white object in strong sunlight might have a luminance of 10,000 ft-lamberts, in artificial room lighting it might be 10 ft.-lamberts and in moonlight it might be 1/100 ft.-lambert.

The cones in the retina, with their high discrimination of colour and detail, act over the range 10^6 to 10^{-3} ft.-lamberts, and the rods overlap this with their range 10 to 10^{-6} ft.-lambert. The lower region where only rods are effective is called scotopic vision, the upper where only cones respond is photopic vision, and the region of overlap, mesopic vision.

The eye cannot see all this range of luminances at once; it needs time to adapt itself to a change in luminance level. Small changes (say by a factor of 5 or 10) can be dealt with relatively quickly by the reflex action of the iris, just as one might alter the aperture of a camera lens. But larger changes involve complicated adaptation phenomena in the retina itself. These processes take time. Thus, after leaving a well-lit room, it may take 10 to 15 minutes to become fully adapted to darkroom lighting.

The eye is sensitive to rays of light over a range of wavelengths from about 380 mμ to about 750 mμ although the useful range is 400 to 700 mμ. The sensitivity varies continuously over this range with a pronounced maximum in the green region of the spectrum, and its plot against wavelength is often called the relative luminous efficiency curve. This is somewhat different for photopic and scotopic vision, the wavelength of maximum sensitivity varying from 555 mμ for the former to 510 mμ for the latter F.J.B.W.

EYE CAMERA. Special motion-picture cameras designed to record the movements of a sitter's eyes when looking at a picture for the first time. The film is analysed to show the order in which the various items and points of interest in the picture attract the attention of the viewer. Records of this type are made in the course of research into the functional value of picture composition and layout.

The term is also applied to the special cameras used in medicine and dentistry for taking close-up pictures—e.g. of the human eye or mouth. Cameras of this type are designed for operation by nurses and assistants without a particular photographic training. The camera is a self-contained unit which may include a built-in flashgun or electronic flash head, some device for centring the subject at a fixed distance from the camera lens and a handle or handles incorporating the shutter release.

On some cameras of this type the subject is located by four pointers attached to the camera body which fix the distance and mark the corners of the field covered by the lens. Or the camera may project a pair of light beams which converge on the subject when it is at the correct distance.

The lens works at a fixed distance setting and once the aperture is adjusted for the speed of the film it never needs to be changed. The duration of the electronic flash is short enough to freeze any movement of the subject or camera and the shutter speed is short enough to prevent a secondary image from being recorded by the ambient lighting.

This type of camera is also used for making record photographs and copying in a number of applications where the size of the subject does not vary much. Since the flash source is mounted close to the camera lens, the lighting tends to be flat and shadowless, but does show full detail of the subject.

EYE CAMERA: Top: The camera has a lens set to a close subject distance and projects two rangefinder beams converging on the same distance. An electronic flash tube below the lens provides the illumination. A, rangefinder windows. B, lens. C, flash tube. D, power pack. Bottom: When the light beams from the rangefinder windows exactly converge on the subject, the latter is at the correct distance for a sharp picture.

F

FABRE, CHARLES, 1867–1945. French physicist. Director of the Institut d'Optique (Institute of Optics), Paris. Writer of books on photography and optics. Biography: *Charles Fabre, Jubilé scientifique*, 3, *December* 1937 (Paris 1938).

FABRIC PRINTING. There are several ways of making a photographic print on fabric. In some methods—e.g., diazotype—the image is produced by dyeing the actual fabric; in others, the fabric is simply used as a support for a silver or pigment image.

Commercial materials. Several manufacturers produce sensitized fabrics for various purposes, ranging from tracing cloths to continuous-tone photo linens.

Sensitized tracing cloth is used in drawing offices to make master positives for dyeline or diazo printing. It consists of a silver chloride or bromide emulsion coated on a varnished or otherwise water-proofed translucent cloth base. The material is exposed and processed like any other document copying material. The finished print usually takes pencil or ink to permit modifications or corrections to the drawing before mass reproduction.

Continuous-tone sensitized fabrics are intended for contact printing or enlarging like any normal photographic printing paper. The emulsion here is impregnated into the fabric (e.g. linen). The latter is semi-stiff when dry, but goes limp on immersion in the processing solutions. It can thus be folded up, making it possible to develop large prints in medium sized dishes. Exposure and processing follow the normal procedure; for drying the material may have to be stretched on frames to ensure a really flat print. Alternatively the dried linen print can be re-wetted and ironed with a household iron set to low heat. (The intermediate drying is usually desirable to ensure that the image is firmly embedded in the fabric.)

Home-made Formulae. There are various formulae for preparing fabrics for daylight or artificial light printing. Most of them yield a contact speed material too slow for projection printing. If the fabric area to be covered is larger than the negative chosen for a print, an enlarged negative must first be made. The negative and fabric are in this case placed in a printing frame for the exposure.

Printing-out Method. The fabric to be printed is first well washed (preferably boiled), immersed in a sizing solution for 3 minutes, and hung up to dry. A formula for a sizing solution is:

Arrowroot	88 grains	5 grams
Sodium chloride	88 grains	5 grams
Glacial acetic acid	¾ ounce	20 c.cm.
Tannic acid	88 grains	5 grams
Distilled water to make	10 ounces	250 c.cm.

The tannic acid is dissolved by boiling in about half the water. The arrowroot is made into a paste with a few drops of water, and the rest of the water is brought to the boil and poured on to it. The other ingredients are then dissolved, and the tannic acid solution is added.

After sizing, the material is immersed for a few minutes in a 10 per cent solution of silver nitrate in distilled water containing 0·1 per cent nitric acid, and dried in total darkness.

It can then be printed out, toned, fixed, etc., like ordinary printing-out paper. The fabric should be handled carefully in the printing frame to prevent it from moving and thus printing double. As a further safeguard, it may be stuck down temporarily with rubber solution mountant on to a sheet of stiff paper.

Diazotype Printing. Diazotype images are based on the decomposition of dye-forming compounds by light. In diazo printing, the final dye image produced after coupling is faintest in the areas of the print that have received the greatest exposure. So a positive transparency must be used to give a positive image in the print.

The fabric to be printed on is soaked in a hot (60-70° C.) 1 per cent solution of primuline (not a primuline dye) for five to ten minutes. During that time it is worked about with a glass rod to ensure thorough penetration and even distribution of the primuline. It is

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

then drained, rinsed in cold water, and hung up, preferably in a current of warm air, until it is quite dry.

It is next immersed (in the dark) in a sensitizer solution containing 0·4 per cent sodium nitrite and 0·6 per cent oxalic acid. This solution must be made up cold and used immediately. The fabric is then blotted between two sheets of blotting paper, and exposed straight away in a printing frame behind the positive transparency.

The material is exposed until a small test piece, exposed directly to the printing light alongside the frame, gives only a slight colour when it is developed.

Still in the darkroom, the exposed fabric is then soaked in one of the developer solutions below, and then thoroughly washed for about thirty minutes.

After exposure the transparency should be washed to remove traces of sensitizer left on it by the moist fabric.

DIAZOTYPE DEVELOPERS

Chemicals	*Concentration of Ingredients and Colours*					
	Yellow	*Orange*	*Brown*	*Red*	*Purple**	*Blue*
Phenol	1%	—	—	—	—	—
Resorcinol	—	0·6%	—	—	—	—
Sodium hydroxide	—	0·9%	—	0·8%	—	—
Pyrogallol	—	—	1·2%	—	—	—
Beta-naphthol	—	—	—	0·6%	—	—
Alpha-naphthylamine	—	—	—	—	1·2%	—
Oxalic acid	—	—	—	—	0·1%	—
Eikonogen	—	—	—	—	—	1·2%

*After this developer the material should be rinsed in a 5 per cent tartaric acid solution, and dried without further washing. Any remaining naphthylamine can be removed from the hands and dishes by rinsing with the sodium nitrite and oxalic acid solution followed by clean water.

Iron-Silver Printing. This method makes use of the action of light in reducing ferric salts to the ferrous state in which they can be made to interact with silver nitrate to produce a silver image. It gives positives from negatives.

The material is immersed, in the dark or by a red safelight, in the following solution and poked about thoroughly with a glass rod for five minutes:

Ferric oxalate	4 ounces	100 grams
Oxalic acid	½ ounce	12·5 grams
Silver nitrate	1½ ounces	37·5 grams
Distilled water to make	20 ounces	500 c.cm.

The oxalic acid and oxalate are dissolved in about half of the water, and the silver nitrate in the rest. The solutions are then mixed when required. The sensitizer is kept in the dark.

After immersion the fabric is drained, dried, and ironed out smooth, all by the light of a yellow safelight of the kind used for contact papers. It is printed out until the image appears about half as dark as required, washed for ten minutes in the darkroom in running water, and fixed in a 5 to 10 per cent plain sodium thiosulphate solution. The process is completed by washing and drying the fabric.

Photo-Mordant Dye-Printing. Fabrics may also be printed by using the photographic image as a basis for a dye. One way of doing this is to wash the fabric well and then sensitize it with a solution of potassium or ammonium bichromate. After drying, the fabric is placed under the negative and exposed to daylight until a faint image appears. This image consists of chromium hydroxide which acts as a mordant for such dyes as alizarine and anthracine. The fabric is simply boiled in a solution of the appropriate dye, cleared in a solution of sodium hypochlorite, washed in soap and water, and dried.

Dyes may also be formed in the fabric by using the chromic acid available in the image to oxidize an organic compound.

Images formed in either of these ways are as permanent as the dyes used. The principle can also be applied to prints on a paper base.

Artificial Light. Fabrics like canvas can be sensitized with an emulsion fast enough for contact or projection printing by artificial light.

All operations, including the preparation of the fabric, must be carried out in total darkness or by a deep red safelight. (Absorption of light by the fabric, even before coating, is said to fog the material.)

The fabric is soaked in soap-suds for about twelve hours, washed well in running water, and dried in the dark. It is then sprinkled with water and ironed with a moderately hot iron. It is next soaked in the presensitizing solution for 20 minutes. A suitable presensitizer is:

Potassium bromide	70 grains	4 grams
Cadmium bromide	½ ounce	12·5 grams
Potassium iodide	70 grains	4 grams
Distilled water to make	40 ounces	1,000 c.cm.

The fabric is then dried and sensitized in the following solution:

Silver nitrate	125 grains	7 grams
Citric acid	30 grains	1·8 grams
Distilled water to make	10 ounces	250 c.cm.

For sensitizing, the fabric is best laid in the bottom of a clean dish. The sensitizer is then poured over it, and any air bubbles are broken up with a glass rod. After about five minutes, the solution is poured off and the fabric is dried in the dark.

The sensitized material can then be treated in the same way as an ordinary bromide development paper. The speed of the emulsion varies with the temperature and other working conditions, so exposures have to be found by trial. L.A.M.

Book: *The Complete Art of Printing and Enlarging*, by O. R. Croy (London).

FACTORIAL DEVELOPMENT. Method of developing by inspection in which the time to the first appearance of the image is multi-

plied by a factor to give the total development time.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The method was first suggested by A. Watkins, in 1893, for which reason the factor is generally referred to as the Watkins Factor. For those who develop by inspection, the method is reliable, although with fast panchromatic materials there is always a risk of fogging as the plate is scrutinized. Each developer has its own factor.

See also: *Developing negatives.*

FADE. Way of starting or finishing a scene in a motion picture film by making it emerge gradually out of darkness (fade in), or darkening it on the screen to complete blackness (fade out).

A fade-out should usually be followed by a fade-in of the next scene. This type of transition implies a passage of time or a change of subject, much like a chapter in a book.

A fade-out superimposed on a fade-in produces a dissolve which often implies a change of location without a change of time, or a transition between related ideas.

In the camera a fade-out can be produced by gradually closing down the lens aperture or reducing the shutter opening of the camera. A fade-in is obtained in the reverse manner. In professional motion picture practice these effects are produced by the film laboratory during printing.

See also: *Cine technique.*

FADING. Disappearance or discoloration of silver image in negatives and prints, especially the latter. It is due to insufficient washing or occasionally to insufficient fixing. With prints, fading may also be due to the use of mountants containing acid or traces of certain oxidizing agents such as free chlorine.

A slightly faded image can sometimes be restored by bleaching it in a permanganate bleacher containing potassium bromide or chloride, followed by a rinse in sodium bisulphite solution, a good wash, and redevelopment in a normal developer (e.g., M.Q. or Amidol). Alternatively, it may be copied on a blue-sensitive film or plate which will tend to reproduce the yellowish faded areas almost as dark as the unfaded ones.

For maximum protection against fading, prints may be toned with sulphide or gold; they are then less easily attacked by oxidizing agents.

See also: *Faults.*

FAHRENHEIT SCALE. System of thermometry (called after its originator, the German physicist G. D. Fahrenheit) based on the mistaken assumption about the coldest temperature attainable. Fahrenheit based his scale on the temperature of a particular freezing mixture, and with that as his zero, he graduated the mercury thermometer to register the boiling point of water as 212°. On this scale, the melting point of ice occurs at 32°. In spite of its unsound basis, the Fahrenheit scale has conveniently spaced degrees for most practical purposes. Until recently the standard temperature scale in Great Britain, it is now gradually being replaced by the Centigrade scale.

See also: *Thermometer; Weights and measures.*

FARADAY, MICHAEL, 1791–1867. English scientist. Showed for the first time a few of Fox Talbot's photogenic drawings at the Royal Institution on 25th January, 1839. He also gave the first public description of the process on this occasion.

Faraday was also interested in "the apparent animate movement of objects from the inanimate", by which he meant the optical illusion caused by the rotation of the phenakistiscope or zoetrope. Biography by S. P. Thompson (1898).

FARMER, ERNEST HOWARD. 1860(?)–1944. English photographer. First Head of the Photographic Department of the Regent Street Polytechnic, London. Invented reducing bath (1883) (Farmer's Reducer) consisting of hypo to which is added ferricyanide of potash. Described in 1894 the reaction between the silver image of a bromide print, bichromate, and gelatin, which is the basis of the bromoil process.

FARMER'S REDUCER. Name sometimes given to the potassium ferricyanide reducer after the originator, E. Howard Farmer.

FASHION PHOTOGRAPHY

Fashions in fashion photography change almost as fast as they do in clothes. In the past few years this branch of photography has been revolutionized in Britain, America and France.

There is a changed market for the fashion industry, and thus for the fashion photographer and the publishers of his pictures. When the glossy fashion magazines started, their market and that of the couture houses which produced fashion, was the rich, sophisticated, middle-aged woman. Her tastes and habits dictated the style of fashion photographs and fashion magazines up to during and just after World War II. Then, the points of interest about a garment were the texture of the cloth, its hang, its decoration, and the setting it was seen in. Techniques—lighting, cameras—were adapted to show these details.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

But since the War, and particularly within the last five years, there has been a great change. A vast new market has appeared: the young wage-earning woman. Her demands are rather different. She wants smart cheap clothes for everyday wear. She is unimpressed by embroidery, decoration, fussiness. So the manufacturer discards the elaborate fabrics and the costly handwork and turns to large volume output. To keep the turnover up, styles must change frequently—hence the importance of the two Collections a year in Paris, London and Italy. Clothes must become obsolete before the next batch is ready for the shops, so very distinctive "looks" follow each other with extreme rapidity.

Today the single, 200 guinea "creation" for the rich woman is almost irrelevant as a commercial article. The change is reflected in today's fashion pictures.

Speaking very generally, there is no time today to appreciate the finer details of a garment. It is made, sold and discarded quickly. So the fashion photographer's function is not so much to create an accurate and attractive visual record of the garment, which will be appraised by critical and well-informed buyers, as to project romance and excitement, to suggest that the clothes have magic sewn into them. Wit and artistic sensitivity have become more important in fashion photography than the traditional expertise of the photographer.

Fashion photography divides broadly into two aspects: editorial and advertising.

EDITORIAL

This branch of fashion photography began in the glossy magazines. Basically the editorial purposes of a fashion photograph are: (i) to inform the reader that a garment exists; (ii) to express a preference—this dress, of the many available has been chosen because the editors feel it embodies an important fashion point; (iii) to contribute to the excitement of the magazine; (iv) to stimulate its manufacturer or seller into buying space in the publication.

Organization. All serious fashion magazines create their own illustrations, that is, "hand out" pictures are never used. On a large magazine a great deal happens before the photograph is taken. The fashion editors on the staff keep a continuous watch on the market, and report trends to the editor. Two or three months before publication day the editor, the art director and the fashion editor decide what kinds of clothes they are going to show, and roughly plan the make up of the magazine: say eight pages of Paris Collections, a spread of cheap winter coats, four pages of ski-ing clothes, and so on. A fashion editor is assigned to each feature, who chooses the actual clothes to be photographed, and gets them together in the office, with all the necessary accessories—hats, shoes gloves and jewellery. The art director assigns a photographer, who, with the fashion editor, engages models. The photographer may work full time for the magazine, or be under contract to produce so many pages a year or he may be a freelance. The art director will also specify whether the photographs are to be taken in the studio or on location.

Photographers. With the change in the emphasis of fashion journalism and photography, photographers have also changed. Five years ago, the successful photographer was typically a mature, artistic, sophisticated man. There are still one or two who survive, but the majority now are in their mid-twenties, from a variety of backgrounds—the east end of London, or a university—but they are in touch with their time and the all-important world of the young, and they know how the young women of our time want to look.

As well as this being in touch with the undercurrents of fashion, he must combine a number of talents. He must be a stage director—for part of his job will be the creation of dramatic tableaux. He must be able to make contact with his sitters—whether professional models, or celebrities, and be able to put them immediately at their ease. He must be able to dissect the fashion qualities of a garment, to analyze its line, texture and mood, and be able to devise poses to bring these out. He has to have a feeling for pictorial composition, be able to flatter the girl and the garment, and create a two-dimensional image that is a harmonious whole in itself. He must be able to put some new quality into every picture he takes. And finally he has to be a competent photographic technician, if no more—though this is perhaps the least important part of the job.

Models. Models are now younger, less supercilious, sexier. The professional demands on them are no less, perhaps even more, and the rewards are immense but, as ever, girls with the right qualities are very scarce. A good model is half way to a good fashion picture, and many photographers work with a very small number of girls, perhaps only one, so that the essential sympathy and understanding between them is maintained. A model and photographer working well together show an almost balletic harmony.

Poses. With the use of miniature cameras, fast films and high aperture lenses, it is no longer necessary for the model to hold a rigid pose. Often she is made to move about while the pictures are taken, and in general her positions will be much more natural and easy than in the traditional fashion picture. As the photographer shoots, the well-trained model will make small alterations in the positions of her head and limbs at the rate of perhaps one a second for exposure after exposure.

Composition. If it is possible to generalize about so diffuse a subject, the modern trend in fashion pictures is towards two-dimensional-ness. This in turn is part of a larger trend towards sim-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

plifying the composition of the pictures, eliminating details and strengthening the basic shapes. The best contemporary fashion pictures seldom try to suggest a real three-dimensional space in which the model exists. Perhaps this can be traced to the influence of the Impressionists and their followers, perhaps it is due to modern layout which demands much greater adaptability to form the elements of a page make-up.

The illusion of depth—a "hole in the page"—which can look up, or down, or be shallower or deeper, only makes pictures more difficult to place beside each other.

Lighting. Nowadays light is seldom used to achieve three-dimensional modelling, but to create pleasing patterns on the printed page. The apparatus of front, three-quarter and back lighting of the classical set-up has been discarded. In its place there is a very simple, standard set-up which can be used in the studio or found on location with ease. In the studio it imitates window light: a bank, placed to one side of the model, between 45° and 90° to the photographer. The model is placed within 4 or 5 feet of a plain mid-tone background, so that her lit side stands out against a darker wall, and her unlit side is seen in silhouette against a brighter wall. If the picture is full length, a paper backdrop is used which rounds off the corner between the floor and wall, and in effect suspends the model in a dimensionless, shadowless, limbo.

This set-up can be seen in almost any issue of any fashion magazine and, of course, it has numerous adaptations.

Another common arrangement uses an even density of light in all directions, from above, behind, below, in front and both sides. This is particularly effective in pictures of diaphonous lingerie, producing a composition of delicate mid-tones against a white ground.

Another trend is to use a ring light round the camera lens, producing a perfectly even flat light, with shadows round the outer edges of the face, limbs, and so on.

Whatever the lighting set-up used, multiple shadows, such as mar much cinema lighting, are never seen, and single shadows very seldom, and then only when they form a definite part of the composition.

On location this approach to lighting means that pictures can be taken under overcast skies, in shadow, inside rooms, or in flat sunlight with equal success. But English weather being what it is, this last seldom occurs.

When light is available on location, artificial aids are seldom used; that is, reflectors, or fill in-flash. The gain in picture quality is offset by the complication of the equipment and the possible ugliness of the results. With most locations, it is always possible to move to find better light.

Equipment. Most fashion photographs are taken with 35 mm. or 2¼ ins. square reflex cameras, and a variety of lenses. Tripods are not often used, and high speed films allow handheld shooting even in the studio. Coarse grain is often needed to give a romantic quality to the finished picture and, in any case, with the fine blocks of a glossy magazine it is no drawback. Lenses from 18 mm. to 1,000 mm. are used with 35 mm. cameras to give either gross distortion or extreme differential focusing and flattening of the image.

Controls. The basic aim of the high fashion picture is the creation of a mood and an atmosphere.

The photograph is only a means to this end, and a great deal of the effect is obtained in the darkroom. To simplify the composition of the picture, contrast is often manipulated, either by sharply increasing it—sometimes so far as to eliminate the mid-tones altogether—or by reducing it. Definition is often decreased, either by using extreme high speed films and force development to produce "golf-ball" grain, or by using a long exposure and moving the camera, or by moving the printing paper under the enlarger. Every photographer has his own favourite techniques, and again generalization is impossible, but it is safe to say that no fashion photographer can afford to neglect dark-room techniques as, say, the photojournalist can.

Locations. Generally it is the decision of the art director whether the pictures are to be taken on location or in the studio, but as pictures tend to concentrate more and more on the clothes and less on their surroundings, the two kinds of picture, which were once very distinct, are beginning to merge. When clothes are photographed outside the studio it is usual now to show them in suitable or neutral settings. Not long ago it was fashionable to use surrealistic backgrounds—e.g. evening dresses photographed in gas-works—but this trend is now over.

Locations in fact present magazines with embarrasing problems. The new fashion picture often requires only the simplest of props—a tree trunk or a spray of leaves may provide all the setting that is needed. But editors are beseiged with offers of free travel from airlines in return for publicity given in the editorial matter.

Thus it may well be cheaper to send a photographer, two models and a fashion editor for three weeks to Japan, than to send the same party for three days in the Cotswolds. But when the Japanese photographs are published, they either look fussy and old-fashioned by showing too much local colour or they show so little of Japan that the airline is dissatisfied.

The foregoing remarks apply to the glossy fashion magazines. They can be extended to fashion photography in other publications by observing that the less sophisticated the surrounding matter, and the less the space available for the fashion pictures, the simpler they will

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

be; also, the poorer the quality of printing the better the photographs have to be, in newspapers, there is no room for extreme high or low key, and definition must be high.

ADVERTISING

As in editorial work there are graduations of technique and interest. Generally though fashion advertising pictures will show the garment more clearly than in editorial pictures; they will attempt to create less of a mood; technique, lighting and models will be more ordinary.

Larger cameras are quite often used and, since an advertising picture has to be suitable for a number of different publications, quality has to be higher. Less freedom is allowed the photographer in choosing his model, pose and lighting—he often has to work from a sketch prepared by the advertising agency. P.La.

Book: *Lighting for Photography*, by W. Nurnberg (London).

FAULTS

The photographic process involves so many variable factors that faults are bound to occur sometimes in its working. These faults may show up in a variety of ways.

Identifying Faults. Before any attempt is made to trace a fault, whether by tables or personal investigation, the fault must first be identified; trouble-shooting charts are useless unless the user knows what type of fault he is trying to track down.

Often the nature of the fault seems clear, but even so, it is better not to jump to a hasty conclusion. The defect should be examined closely—through a magnifier if necessary—and all peculiarities, however slight, should be noted. Any unusual circumstances which can be related to the fault, even remotely, should be borne in mind—e.g., very cold weather, a stock clearance bottle of developer, a sticking dark slide.

Tracing Faults. The more common photographic faults will be found in the tables that follow. The major faults which appear in these tables are also dealt with in detail in separate articles and information on these in the tables is therefore abbreviated. However, faults can be caused by so many things that it is almost impossible to anticipate every one.

If a fault cannot be traced in the tables, systematic investigation should reveal the cause.

First it is necessary to establish the stage of the process at which the fault occurred. This narrows the field and eliminates any causes outside that particular stage—e.g., to establish if horizontal black lines across a print occurred when the print was made, the negative is first examined. If this reveals similar, but clear lines, the print-making stage is at once cleared from blame. Black marks on the negative that only appear in the picture area and not in the border left by the rebate in the camera indicate that the trouble could have only happened when the film was in the camera with that part of the negative in position in the film aperture. By further investigations, other possibilities are similarly eliminated until the source of the trouble is revealed.

Often, however, such a methodical system points to more than one answer. A fault may arise at any one of several stages—e.g., excessive grain might be caused by faulty film material, over-exposure, unsuitable developer, high processing temperatures, etc. When this happens it may be possible to eliminate some causes—e.g., over-exposure would show other signs as well—but failing this, the only course available is to check each stage.

Similarly, faults in colour balance in a colour print may be due to errors in the colour correction during printing, or they may already be inherent in the colour negative (for example lack of balance due to mixed lighting). Such faults are more difficult to establish directly from the negative, and only become apparent if correction of a fault in a colour print inevitably gives rise to other errors in colour rendering in subsequent prints.

If no satisfactory solution can be found in this way, photographic publishers and manufacturers are usually willing to give advice if full details are provided.

FAULTS IN BLACK-AND-WHITE NEGATIVES

Description	*Cause*	*Treatment*
Image lacks detail in shadows	Under-exposure	Density of any faint detail present can be improved by intensification
Image weak and flat, but reasonable detail in shadows	Under-development	Intensification or make a contrasty duplicate negative (optical intensification)
Image dense, shadows veiled, highlights very flat but dense. Border of negative clear	Over-exposure	Subtractive reduction
Image hard, with particularly dense highlights but good contrast and detail in shadows	Over-development	Proportional reduction

FAULTS IN BLACK-AND-WHITE NEGATIVES

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Description	*Cause*	*Treatment*
Image extremely thin, very little detail, especially in shadows, very weak contrast	Under-exposure and under-development	Difficult to improve. Intensification or make a contrasty duplicate negative (optical intensification)
Image hard with very little detail in shadows	Under-exposure and over-development	Super-proportional reduction to reduce highlights, then intensify to improve shadows
Very little contrast and absence of strong densities but plenty of detail in negative	Over-exposure and under-development	Proportional reduction to lower over-all density, then intensify to increase contrast
Image extremely dense all over with no clear celluloid or glass except around rebate	Over-exposure and probably over-development	Proportional reduction
Image fades after some time and/or turns brown	Insufficient washing and/or fixing	If deterioration not too advanced, bleach in halogenizing bleacher and redevelop in ordinary developer
Image and emulsion vanish during after-treatment in certain solutions	Excessive immersion times in acidified baths, or use of baths too strongly acid	None
Partial or complete reversal of negative to a positive image	Accidental fogging, possibly due to unsafe darkroom light, before or during development	None
Negative shows over-all veil, particularly in shadows; no clear celluloid or glass visible		
(1) Borders of negative perfectly clear	Over-all fogging occurring when negative was in camera. Caused by faulty shutter or light leak	Subtractive reduction to clear shadows
(2) Borders of negative also veiled	Over-all fogging due to excessive development time; developer temperature too high; developer exhausted; developer incorrectly mixed; unsafe darkroom light; light leaks in camera back, film packing, darkroom or processing tank; faulty sensitized material due to staleness, packing, etc.; or aerial fog due to excessive exposure to air during development	Subtractive reduction to clear shadows
Over-all fog on negative (including borders) which appears red by transmitted light and blue by reflected light	Dichroic fog, due to developer exhaustion or contamination with hypo; developer too warm or development time too long; too high sulphite content in fine-grain developers; fixing bath exhausted or too warm; fixing bath contains excess of carried-over developer due to exhausted stop-bath or insufficient rinse; or negative exposed to strong white light before completely fixed	Bathe negative in solution of thiourea and citric acid (1–2 per cent each) in water
Image very dull and clear areas obscured; back of negative has brownish appearance	Insufficient fixing	Refix and wash
Over-all fog which is yellow by transmitted light	Similar to dichroic fog	As for dichroic fog
Edge of negative shows black fog, tailing off towards centre of negative	Light leak due to faulty plate-holder or camera back; roll film loosely wound or exposed excessively to daylight during loading, unloading or storage; or red window in camera unsafe	Use abrasive reducer or retouch on print
Numbers and other markings from roll film backing paper appear as image on film	Badly stored or stale film	In slight cases, retouch negative or print
Irregular, forked or tree-like wavy black lines, sometimes resembling lightning	Fogging caused by static electricity discharged when roll film is unrolled quickly in very dry weather.	Retouch on negative or print
Black lines or smudges over image, but not on borders of negative	Pinhole in bellows or camera body	In very slight cases retouch print

FAU

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Description	Cause	Treatment
On films only, very short black lines, right-angled and thinner at ends; sometimes coinciding with identical depression on film surface	Cinch mark, due to film buckling	Retouch on negative or print
Image has light streaks or lines around the edges of dark areas or running in straight lines from dark areas; or, similarly, dark lines on light areas	Mackie lines, due to insufficient agitation of developer, causing local concentration of exhausted developer	In slight cases, retouch negative or print
Density irregular and streaky	Insufficiently mixed or unstirred developer; or insufficient agitation during development	None
Thin, dark or light straight scratches on negative	Abrasion marks or scratches, due to dust, grit or faulty film loading. Light scratches usually occur before exposure, dark scratches after exposure	In slight cases, negative or print may be retouched
Large, irregular, light areas with sharp edges	Unequal flow of developer during processing, causing uneven development	None
Irregular areas of higher density	Variations in developer concentration or temperature, due to addition of developer during development	None
Irregularly defined light areas, often contaminated with scum	Developer standing unprotected from dust and air, causing a scum of oxidation products which locally retard development	None
Regular wave-like markings on dish developed negatives	Insufficient agitation during development	None
Speckled and mealy unevenness of image density	Deterioration resulting from damp storage or staleness of material, or use of old developer	None
Gradual increase in density towards one end of negative; with plates, sometimes very noticeable at edges	(1) Uneven drying (2) Faulty focal plane shutter	Depending on extent, negative may be "shaded" during printing
Edges of high densities (bright parts of subject) spreading into lower densities	Irradiation, due to light scatter in emulsion	In slight cases, retouch negative or print
Halos or rings around very high densities (usually light sources in the picture)	Halation, due to reflection of light from negative support, particularly with glass plates	In slight cases, retouch negative or print
Curved lines of increased density; may be accompanied by star-shaped images	Lens flare	Use abrasive reducer or retouch on negative or print
Finger marks		
(1) Light marks	Negative contaminated with grease or fixer from fingers before development	In slight cases, retouch negative or print
(2) Dark marks	Negative touched before development, with moist finger-tips, or fingers contaminated with developer	In slight cases, retouch negative or print
Small, usually well defined, light or dark spots	Ordinary or chemical dust on negative before development	Retouch negative or print
Clear, light, circular spots with soft edges	Air-bells on negative during early stages of development	Retouch negative or print
Small dark or light flecks of irregular shape	Particles of undissolved chemicals in developer	Retouch negative or print
Small, light, undefined brownish specks	Over-used and insufficiently agitated developer	Retouch negative or print
Light or dark drop-like densities, sometimes with darker edges	Drying marks, due to persistent drops of water when remainder of negative is dry; or splashes of water when negative is dry	Sometimes removed by thorough re-washing; wipe away all surplus water before drying again
Black specks of foreign matter in emulsion	Grit in processing solutions (particularly washing water); or dust in drying	Do not attempt to wipe away persistent specks; retouch print
Small, clear holes in emulsion	Black specks in emulsion which have been dislodged and washed or wiped away	Spot out hole with blocking out medium; retouch print

FAULTS IN BLACK-AND-WHITE NEGATIVES

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Description	*Cause*	*Treatment*
Holes or hollows in surface of negative	Due to insects, bacteria or moulds, particularly during long drying times in warm, moist weather	In slight cases, retouch negative or print
Small blisters in emulsion	Usually due to transferring negative from highly alkaline developer to strongly acid stop bath or fixer	Prick blisters with needle before dry, or retouch print
Emulsion leaving negative support (liable to occur with plates), particularly at edges	Frilling; often a manufacturing fault but may also be caused by same reasons as blisters; or by excessive handling of edges with warm fingers	Carefully replace emulsion before dry
Image distorted and emulsion melting	Excessively high temperatures during processing or drying	None
Surface of negative dries with a fine grain-like pattern in emulsion surface. Often feels rough when dry	Reticulation, due to sudden changes in temperature between different processing solutions	None. When gelatin anti-curl backing on roll film reticulates, it will not usually show on prints
Negative appears opalescent and yellowish-white	Sulphur from decomposing fixer, due to excess of acid; high temperature; or insufficient sulphite in acetic acid fixers	Harden in 1 per cent formalin and then bathe in 10 per cent solution of sodium sulphite at about 100° F.; wash well
Fine-grained white deposit	Chalky residue from very hard water	Bathe negative in 2 per cent solution of acetic acid; wash well
On wet negatives, shiny deposit which dries with a white powdery appearance	Precipitate of aluminium sulphite, due to fixing bath losing acidity	Harden in 1 per cent formalin and then bathe in 5 per cent solution of sodium carbonate; wash well
Surface of negative has frosty deposit	Insufficient washing after fixing	Re-wash
Streaky markings similar to appearance of oil on water	Dirty or contaminated dishes or tanks used in processing	Bathe negative in 1–2 per cent solution of acetic acid
Red, blue or green tinge on negative support	Anti-halation backing, which should normally disappear during processing	If colour is deep or uneven, soak negative in 5 per cent sodium sulphite solution

FAULTS IN BLACK-AND-WHITE PRINTS

Description	*Cause*	*Treatment*
Flat tones showing insufficient contrast but adequate detail in highlights	(1) Contrast grade of paper too soft for negative used (2) Print was over-exposed and under-developed (3) Developer too dilute or too cold	No satisfactory remedy, make new print
Tones too light but show evidence of correct contrast	(1) Paper was under-exposed (2) Developer exhausted (3) Print was slightly under-developed	No satisfactory remedy, make new print
Tones very contrasty with little detail in highlights; shadows dense	(1) Contrast grade of paper too hard for negative used (2) In slight cases, print under-exposed and over-developed	No satisfactory remedy, make new print
Over-all heavy tones with veiled highlights	(1) Print was over-exposed (2) Developer too warm (3) Severe over-development	No satisfactory remedy, make new print
Tones show good contrast and quality but highlights not clean	(1) Print slightly over-exposed and/or over-developed (2) Very slight fogging	Very short immersion in Farmer's reducer
Image and print borders fogged all over	(1) Unsafe darkroom safelight (2) Unsafe enlarger safelight filter (3) Stray white light from enlarger or, during exposure, reflection from light walls, etc. (4) Darkroom not thoroughly blacked-out (5) Paper stale (6) Developer contained insufficient potassium bromide, was too warm or too concentrated	No satisfactory remedy, make new print
Tones are a greenish-black colour	(1) Chloride and bromide prints under-developed (2) Chlorobromide prints over-developed (3) Developer exhausted (4) Excess of potassium bromide in developer	Print may be toned if colour is objectionable

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FAULTS IN BLACK-AND-WHITE PRINTS

Description	*Cause*	*Treatment*
Prints turn yellow on keeping	(1) Incompletely fixed or insufficient washing after fixing (2) With mounted prints, mountant used contains free acid, or impurities present in mount	Bleach in concentrated halogenizing bleacher and redevelop in ordinary developer
Prints turn yellow or brown during processing	(1) Excessive development (2) Developer contaminated with hypo or containing insufficient potassium bromide (3) Developer too warm (4) Insufficient rinse between developing and fixing (5) Fixer insufficiently acid, possibly due to developer contamination	Try developer stain remover
Yellow or brown stains	(1) Inefficient agitation or prints stuck together during fixing (2) Exposure to white light before fixing was complete (3) Insufficient rinse between developing and fixing (4) Exhausted or insufficiently acid fixer	Bathe in appropriate stain remover after refixing and rewashing in cases (1) and (4)
Brown marks on hot glazed prints	Insufficient fixing or washing	In some cases, bleach in a potassium permanganate bleacher and then redevelop, wash and dry
Sharply defined patches of uneven density	Print not completely covered by developer at beginning of development	None
Blotchy, uneven density with very flat contrast	Development time much too short	None
Surface has white streaky scum	(1) Dirty dishes (2) Hard water used in washing	Immerse in bath of 2 per cent acetic acid
Small, black spots, clearly defined; no corresponding spots on negative	(1) Undissolved chemicals in developer (2) Air bubbles in rinse, stop bath of fixer	Retouch
Small white spots, clearly defined; no corresponding spots on negative	(1) Air bubbles in developer (2) Small impurities in paper	Retouch
Irregular and concentric ring shaped markings	Newton's rings, due to minute gap between negative and enlarger carrier glasses	Retouch
Blisters in emulsion	(1) Differences in temperatures of processing solutions too great (2) Differences in alkalinity of developer and acidity of stop bath or fixer too great	In slight cases, remove loose emulsion and retouch with medium thickened with gum
Fine, short black lines	Stress marks, due to pressure or creasing on emulsion	Retouch
Mottled tones, although print was fully developed	Stale paper	None, but stale paper can be used if a developer improver is first added to developer
Greenish image tones	Under-development, exhausted developer, or stale paper	Tone in direct gold tones; can be avoided by use of developer improver
Black or fogged edges	Paper stored in damp or very warm room, or near gas stove or fire from which gas has reached paper	None, but in slight cases paper can sometimes be used if developer improver is first added to developer
Image reversed left to right	Negative placed wrong way up in enlarger or printing frame	None

FAULTS IN THE PICTURE

Description	*Cause*	*Treatment*
Image blurred all over	(1) Incorrect focusing of camera or enlarger (2) Camera or enlarger shake	None
Image consistently blurred in one area	Film plane not flat, due to opening bellows too sharply with film cameras; distorted camera back or plate holders; faulty loading of plates or films; or weak or broken pressure plate in roll film cameras	None

FAULTS IN THE PICTURE

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Description	*Cause*	*Treatment*
Moving objects blurred	Shutter speed too slow to arrest movement	None
Near objects sharp, far objects blurred, or vice versa	Insufficient depth of field, due to using too large lens aperture	None, but with some subjects it can be used intentionally to subdue unwanted parts of picture
Image blurred and flat in contrast all over	Lens misted over, due to condensation when cold lens is brought into contact with warm air. Dirty lens	None
Picture confined to circle shape, image dark and blurred	Lens not extended on cameras fitted with collapsible mount	None
Out-of-focus blob intruding into picture area on some or all pictures	Holding camera so that hand or fingers obstruct lens; flap of ever-ready case obstructing lens; or wide-angle lens used in plate camera without wide-angle rack	None. In slight cases, exclude in masking of enlargement
Dark corners	Unsuitable lens which does not cover complete negative area. If edges are pronounced, lens hood of wrong design used, or rectangular lens hood fitted on incorrectly.	In slight cases, exclude in masking of enlargement or shade during printing
Framing of subject consistently inaccurate	(1) Viewfinder mounting out of adjustment (2) Wrong viewfinder for lens fitted on camera (3) Faulty sighting with frame type viewfinders (4) Failure to compensate for parallax errors	None
Two different images in same picture	Double-exposure	None
Moving parts of subject appear in picture twice as double image	Shutter bounce, due to shutter bouncing momentarily open after initial exposure	None, but have shutter examined by reliable camera repairer
Dimensions of subject distorted	(1) Foreshortening, due to using viewpoint too close to subject (2) Distortion due to lens	None, but in the case of (1), a more distant viewpoint should have been chosen
Clouds in skies fail to register clearly	Relative over-exposure of sky which could be avoided by using filter	Give sky extra exposure during printing

FAULTS IN COLOUR TRANSPARENCIES (POSITIVES)

Description	*Cause*	*Treatment*
Image too light and colours weak	(1) Over-exposure (2) Incorrect processing, especially if excess of one colour is present in tri-pack materials	Only (1) can be treated, in the case of additive transparencies, by intensification
Image too dark	(1) Under-exposure (2) Incorrect processing, especially if colour rendering is inaccurate	Additive transparencies may be improved by reduction. With tri-pack materials, manufacturer may suggest satisfactory formulae for treatment
Highlights burnt-out or shadows blocked-up	(1) Brightness range of subject too great (2) Incorrect processing	None
Image excessively orange in colour	(1) Daylight film used in artificial light. This is most likely cause (2) Incorrect processing	Try binding pale blue filter tint over transparency
Image excessively blue in colour	(1) Artificial light film used in daylight. This is most likely cause (2) Incorrect processing	Try binding pale pink filter tint over transparency
Image consists almost entirely of one colour only	(1) Monochrome filter left over camera lens (2) Incorrect processing (3) Coloured light used (4) Sheet film exposed through base	None

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FAULTS IN COLOUR TRANSPARENCIES (POSITIVES)

Description	Cause	Treatment
Some colours correct, others unaccountably false	(1) Uneven or mixed lighting used for subject (2) Vapour discharge lighting used for subject (3) Colour casts reflected from objects near subject	None

FAULTS IN COLOUR NEGATIVES

Description	Cause	Treatment
Image too light	(1) Under-exposure (2) Under-development of film (3) Exhausted or wrongly compounded developer (4) Stale film	None
Image too dark	(1) Over-exposure (2) Over-development or excessive temperature	None
Image very contrasty	Over-development	None
Areas of uneven density	Insufficient agitation during development	None
Stains and blotches	(1) Exhausted developer (2) Insufficient agitation (3) Contamination of bleacher or bleach-fixer by developer (4) Fogging or reflections in camera	None
Strong overall stain	(1) Orange stain: dye mask in film (2) Other stains: incorrectly compounded developer	(1) This is normal for certain films and is not a fault, hence requires no treatment. The dye mask colour however makes the already difficult job of estimating colours in a negative virtually impossible. (2) None
Negatives clear very slowly in bleacher, or not at all.	Exhausted bleacher	Repeat processing stages starting with bleaching in fresh solutions
Overall opalescent yellowish appearance of film	Insufficient time in bleacher or exhausted solution	Repeat processing steps starting with bleacher in fresh solution
Grainy appearance on film surface	Reticulation due to processing solutions being at different temperatures	None
Clear spots on film	(1) Dust in the camera (2) Undissolved particles or sediments in the developer adhering to the film, or air bells due to insufficient agitation at start of development	With care may be retouched on the print, or even on the negative in the case of large formats
Scratches	Careless handling of film when hanging up to dry or during processing	Retouching in negative or print

FAULTS IN COLOUR PRINTS FROM COLOUR NEGATIVES

Description	Cause	Remedy for subsequent prints
Image too dark	(1) Over-exposure (2) Over-development or too warm developer	(1) Reduce total exposure (or three exposures in proportion for three-exposure printing if colour balance is correct) (2) Check solution temperatures and carefully observe recommended colour development time
Image too light	(1) Under-exposure (2) Under-development (3) Exhausted or too cold developer	(1) Increase total exposure and check that exposure increase of filter factors has been allowed for (2) Keep to recommended development time (3) Check development temperature and use fresh solutions
Image shows predominant overall tint	(1) Incorrect filtering in single-exposure white-light printing (2) Incorrect balance of exposures in three-exposure additive printing	(1) Add or increase filter density of colour corresponding to cast (or decrease filter densities of other two colours); in case of predominant casts of primary colour (red, green or blue), decrease filter density of complementary colour or increase densities of other two colours (2) Increase exposure through tricolour filter of same colour as cast or decrease exposure through other two filters; in case of complementary casts (yellow, magenta or cyan) decrease exposure through complementary primary filter (blue, green or red respectively) or increase exposure through other two filters

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FAULTS IN COLOUR PRINTS FROM COLOUR NEGATIVES

Description	*Cause*	*Remedy for subsequent prints*
Cyan cast or dirty yellows which cannot be removed by filtering correction or requires disproportionately heavy cyan filtering or short red filter exposure	Infra-red radiation affects red sensitive layer of paper	Use heat filter or infra-red absorbing filter between lamp and negative in enlarger
Colours wrong only in highlights and/or shadows, or specific areas of picture, impossible to correct fully by adjusting printing exposures	(1) Negative under- or over-exposed (2) Negative under- or over-developed (3) Subject exposed by mixed lighting (for example daylight and artificial light)	(1) Measure exposures carefully (2) Keep to recommended development of colour negative, especially development time (3) Always illuminate the subject only with light sources of the same colour temperature
Final print does not correspond in depth or colour balance to test on which it was based	(1) Test and final print made under different conditions (2) Unnoticed variations in enlarger lighting, processing solutions, etc. (3) Different batches of colour paper used for test and for final print	(1) Keep careful notes of filtration and exposure for all tests and check that optimum values established for test are also repeated for final print (2) Use a voltage stabilizer in the enlarger lighting circuit; develop final print in same developer as used in test, and check that developer is not getting progressively exhausted
Image dull and lifeless	(1) Negative too soft (2) Print under-developed or processed in exhausted developer	(1) Use a contrasty grade of colour paper (if available), or make both test and final print with longer development, adjusting filtration accordingly to correct change in colour balance (2) Increase development time and/or replace developer if necessary
Image harsh and contrasty, detailless highlights and heavy shadows	(1) Negative too contrasty or under-exposed (2) Print over-developed	(1) No remedy, though sometimes reduction of development time for test and for final print with corresponding adjustment of filtration may produce passable result (2) Decrease development time
White borders and highlights stained or veiled	(1) Stale or exhausted developer (2) Excessively high processing temperature (3) Insufficient rinsing before bleach fix bath (4) Stray light in darkroom or paper exposed too near to safe-light (5) Exposure to white light before bleaching is complete (6) Incorrectly compounded developer	(1) Use fresh developer (2) Observe recommended processing temperature (6) Use maker's recommended processing chemicals. If this does not help, add 0·1% hydroxylamine hydrochloride to colour developer
Highlights stained, but borders clean	(1) Over-exposure of print (2) Stray light during exposure in enlarger	(1) Reduce exposure (and adjust filtering if necessary)
Irregular patches or streaks	(1) Prints sticking together in processing solutions (2) Prints handled with fingers during processing (3) Fogging by light	(1) Keep prints moving about continuously, especially in colour developer (2) Avoid contaminating solutions with each other (3) Use maker's recommended safe-light and avoid examining prints too close to safe-light before completion of bleach
Discolouration of parts or whole of print when dry	(1) Insufficient fixing or exhausted bleach fix bath (2) Prints hot glazed or dry mounted by heat	No remedy
Colour fringes and blurred outlines near edges of print	Enlarger lens or (if fault present on negative) camera lens not sufficiently corrected for colour	No remedy
Colour fringes and blurred outline all over print	(1) Enlarger vibration during exposure (2) Enlarger or paper slightly moved when changing filters	(1) After last touching enlarger wait for a few seconds before starting exposure (2) Check enlarger set-up for rigidity

FAULTS IN REVERSAL COLOUR PRINTS FROM TRANSPARENCIES

Description	*Cause*	*Remedy for subsequent prints*
Image too light	(1) If associated with blank highlights: over-exposure (2) Associated with high contrast: excessive first development (3) Associated with low contrast: insufficient colour development	(1) Reduce printing exposure (or exposures when using additive printing method) (2) Check temperature and time of first development (3) Check temperature and time of colour development (also use fresh solutions)

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FAULTS IN REVERSAL COLOUR PRINTS FROM TRANSPARENCIES

Description	*Cause*	*Remedy for subsequent prints*
Image too dense	(1) With blocked-up shadows: under-exposure (2) With low contrast: insufficient first development (3) With high contrast: excessive colour development	(1) Increase exposure (through all three filters in proportion when using additive printing method) (2) Observe recommended time and temperature in first developer, and use fresh solutions
Image too contrasty with blank highlights and blocked shadows, usually also with falsified colours in parts of picture	Transparency too contrasty for printing	No simple remedy; reduce contrast of transparency by masking or make prints by negative positive process via an internegative
Overall colour cast	(1) Incorrect filter combination with white-light printing method (2) Incorrect balance of exposures through tricolour filters with three-exposure printing (3) Fogging in darkroom	(1) Reduce filter density of same colour as cast or increase filter densities of other two colours; in case of primary (red, green or blue) casts increase filter density of complementary colour (cyan, magenta or yellow respectively) or reduce filter density of other two colours (2) Decrease exposure through tricolour filter of same colour as cast or increase exposure through other two filters; in case of magenta, cyan or yellow casts increase exposure through complementary primary filter (green, red or blue)
Generally degraded colours	Transparency unsuitable for printing owing to colour faults or inherent colour cast which cause further deterioration in reversal print	No remedy

FAULTS IN GLAZING AND MOUNTING

Description	*Cause*	*Treatment*
Prints stick and cannot be stripped when dry	(1) Glazing sheet was dirty (2) Glazing solution exhausted	Soak in water to remove and then re-glaze
Unglazed spots on surface of glazed print	(1) Air bells trapped between print and glazing sheet (2) Squeegee applied too heavily or too lightly (3) Dirty glazing sheet	Soak in water and then re-glaze
Glazed surface shows oyster-shell markings	Uneven drying	Soak in water and then re-glaze
Glazed surface covered in fine scratches	Glazing sheet covered in fine scratches	Soak in water and re-glaze print on new glazing sheet
Prints refuse to glaze	Prints left for too long in an acid hardening fixer	None
Wet mounted prints will not stick	(1) Too little, or more likely too much mountant used (2) Print applied to mount before mountant was tacky	Remove immediately, clean and re-mount
Dry mounted prints will not stick		
(1) Tissue sticking to mount, but not to print	(1) Too much heat	Adjust temperature or time of pressing
(2) Tissue sticking to print but not to mount	(2) Insufficient heat or too short pressure	
Dry mounted prints only sticking in places	Uneven application of heat or pressure	When due to too much heat, it is better to allow print to cool for a few seconds before trying again
Dry mounting tissue will not stick to either print or mount	(1) Stale tissue (2) Iron or press not hot enough	(1) None (2) Check equipment
Dry mounting tissue protruding from edges of mounted print	(1) Print not absolutely dry before mounting (2) If tissue was trimmed after tacking on to print, trimmer blade may have pulled tissue and print unevenly, trimming more of latter	May be removed by carefully trimming with razor blade, then pulling cut strip free of mount
Mounted prints have slightly uneven surface or light creases	Too much wet mountant or creases in dry mounting tissue	In some cases, print may be removed, cleaned and re-mounted
Cockling—i.e., small areas of print leaving mount and swelling into irregular hump shapes	Moisture in print or mount before dry mounting	If print can be removed: clean, wash and dry thoroughly; ensure mount is perfectly dry; then re-mount print. Sometimes, with dry mounting, can be removed by applying heat with heavy pressure

FAULTS IN GLAZING AND MOUNTING

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Description	Cause	Treatment
Surface or image of print damaged by dry mounting	(1) Type of print unsuitable for dry mounting—e.g., carbro prints, tri-pack colour prints	(1) None
	(2) Glazed prints dry mounted with textured surface between print and heat source	(2) Remove print and re-glaze and re-mount
Dye retouching shows after mounting print	Colour of dye changed by heat; dye retouching should be done after mounting	Some improvement possible by retouching again
Colour prints partially or wholly discoloured after glazing or mounting	Colours attacked by heat	None

FEDERATION INTERNATIONALE DE L'ART PHOTOGRAPHIQUE. International movement officially launched in 1947 with the broad aims of raising the status of amateur photography as a common cultural link between nations, improving photographic techniques by the interchange of ideas, and contributing, by its international associations, to world peace.

There are affiliated associations in a large number of countries spread over both hemispheres, and representatives meet and exchange views at periodical gatherings. The Fédération organizes a biennial international photographic exhibition and issues monthly bulletins to members. These bulletins draw attention to matters of technical interest in the photographic press and give members regular reports on the work of the branches and committees.

Prints from the biennial salon are circulated for exhibition to affiliated associations throughout the world with the object of letting not only photographers, but the ordinary citizen of each nation learn something of the activities of other nations in a language that all can understand. The Fédération publishes a yearbook of representative photographs following the biennial exhibition.

FEERTYPE. Process invented by Dr. Adolf Feer in 1889. Paper is sensitized with a diazo compound which forms a coloured salt when exposed to light. The paper is exposed under a negative and washed to remove the unused chemicals, leaving a positive image in the selected colour.

See also: *Printing processes (obsolete).*

FEES. Prints accepted for publication in the press or any form of illustrated literature—e.g., travel guides, catalogues, brochures—are paid for at rates which vary according to the publication, size of reproduction, etc.

Prices charged for taking photographs—e.g., for commercial or private customers—depend on the type of work undertaken, the number and size of the prints supplied, and numerous other factors such as local supply and demand.

FENTON, ROGER, 1819–69. English barrister; from 1847 till 1862 architectural, landscape and portrait photographer. Founder and first Honorary Secretary of the (Royal) photographic Society (1853). The first to photograph war scenes under fire and to take the actual battlefields. Sailed from England in February 1855 as accredited war photographer for the Crimean War and took during the spring of 1855 over 350 photographs. Biography by H. & A. Gernsheim (London 1955).

FERGUSON, WILLIAM BATE, 1853–1937. English scientist; member of the Research Laboratory of Ilford Limited. With B. E. Howard he worked out the time and temperature method of development (1906). Received the Progress Medal of the Royal Photographic Society in 1914 for his researches, discoveries and publications on the physics and chemistry of photography. He edited the *Hurter and Driffield Memorial Volume* of the R.P.S. (London, 1920).

FERRI. (Slang.) Abbreviated term for potassium ferricyanide; usually applied to reducers containing ferricyanide.

FERRIC ALUM. Ferric ammonium sulphate. Constituent of some blue and blue-green toners and reducers.

See also: *Alum, Iron.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

FERRIC AMMONIUM CITRATE. Used in certain sensitizers and toners.

Characteristics: Brown or green crystals of slightly variable composition. The brown variety is the more basic one. Both are slightly sensitive to the action of light.

Solubility: 20–30 parts in 100 parts of water at room temperature.

FERRIC AMMONIUM OXALATE. Used in certain sensitizers (e.g. in the blue-print process) and toners.

Formula and molecular weight: $Fe_2(C_2O_4)_3 . 3(NH_4)_2(C_2O_4) . 6H_2O$; 856.

Characteristics: Green crystals. The salt, particularly in solution, is sensitive to light.

Solubility: Highly soluble in water at room temperature.

FERRIC AMMONIUM SULPHATE. Constituent of some reducers and toners for blue and blue-green images.

See also: *Alum, Iron.*

FERRIC CHLORIDE. Iron chloride. Used in reducers, various iron (blue print) and iron-silver processes and as etching mordant for copper, for processes such as mezzotints and photomechanical work.

Formula and molecular weight: $FeCl_3 . 6H_2O$; 270. Also available as the anhydrous salt $FeCl_3$; 162.

Characteristics: Yellow very deliquescent crystals.

Solubility: Highly soluble in water. The anhydrous salt is also freely soluble in alcohol, ether, and other organic solvents.

FERRIC OXALATE. Used in certain sensitizers (e.g. in the blue-print process) and toners.

Formula and molecular weight: $Fe_2(C_2O_4)_3 . 6H_2O$; 484.

Characteristics: Greenish crystals. The solution is sensitive to light.

Solubility: Fairly soluble in water.

FERRIC POTASSIUM OXALATE. Used in sensitizers for iron processes; also in blue toners.

Formula and molecular weight: $Fe_2(C_2O_4)_3 . 3K_2(C_2O_4)_2 . 6H_2O$; 982.

Characteristics: Green crystals. Solution sensitive to light.

Solubility: Fairly soluble in water.

FERRO-PRUSSIATE PROCESS. Little used for ordinary photographic printing; it is mainly employed for reproducing plans and drawings, which are commonly called blue prints. The paper is sized and then sensitized in equal parts of the following solution, mixed just before use:

Stock solution A		
Ferric ammonium citrate	10 ounces	250 grams
Water	40 ounces	1,000 c.cm.
Stock solution B		
Potassium ferricyanide	3½ ounces	90 grams
Water	40 ounces	1,000 c.cm.

The made-up solution should be kept in the dark.

The paper is pinned to a board and a liberal quantity of the sensitizing solution is applied with a brush or clean sponge. After sensitizing, the paper is dried in the dark.

The dried paper is held in contact with the plan, drawing or negative to be printed and exposed to daylight or arc light. Printing is slow and should be carried on until the shadows attain a bronze tint. The blue print is developed by simply soaking it in two or three changes of clean water.

See also: *Document copying.*

FERROTYPE PROCESS. Method for making direct positive prints in the camera on black or chocolate enamelled iron plates (called ferrotype plates). A variation of the Ambrotype, introduced by A. A. Martin in 1853 and very popular in the United states in the 1860s. In Europe chiefly used by street, beach and itinerant photographers. The plates were originally coated by the wet collodion process but dry plates were later manufactured.

The ferrotype process was popular for while-you-wait photography since there was no time wasted in drying the base. Since the original image is converted into a positive and there is no intermediate negative, it is reversed from left to right—a fact that the while-you-wait photographer rarely pointed out to his customers.

FERROTYPING. American name for the process in which photographic prints on bromide and contact paper are glazed by squeegeeing them into contact with a highly polished surface. At one time the most convenient surface was provided by sheets of japanned iron (ferrotype plates) specially produced for the purpose. Nowadays sheets of highly-polished chromium-plated steel, stainless steel, or plastic, are favoured because they are less easily damaged than ferrotype plates.

FERROUS OXALATE. Used as a developing agent, but now obsolete.

Formula and molecular weight: FeC_2O_4; 144.

Characteristics: Yellow salt. Generally prepared in solution by adding ferrous sulphate solution to excess potassium oxalate solution. The solutions do not keep well.

Solubility: Insoluble in water, but soluble in solutions of potassium oxalate.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FERROUS SULPHATE. Green vitriol. Used in certain clearing and stain removing baths.

Formula and molecular weight: $FeSO_4.7H_2O$; 278.

Characteristics: Green crystals.

Solubility: Freely soluble in water at room temperature. Does not keep well in solution.

FIBRE-OPTICAL SYSTEM. Optical system using glass fibres and fibre arrays as light-guides and for relaying images.

Light-guides. A light-guide is a transparent rod having polished surfaces coated, whenever practical, with material of lower refractive index to protect them. Light entering the end face is refracted towards the axis. Light incident within a certain cone becomes sufficiently oblique to the cylindrical surface to be totally internally reflected there by the refractive index difference between core and coating. It is thus trapped and zigzags down the core of the light-guide until it is refracted out of the far end.

Such guides still transmit light when they are bent over radii more than a few times the diameter of the guide itself. They also transmit well, down to a diameter of ten wavelengths or less, given a coating of two wavelengths' thickness.

Light may therefore be guided down flexible fibres of optical glass a few ten-thousandths of an inch across and several feet long. In these guides there are several hundred reflections per inch along the length. Light would be almost completely absorbed during this number of reflections from a metal mirror.

Image-transmitting Fibre Bundles. Consider a close-packed array of fibrous light-guides in which the position of each fibre in the array is the same at its two ends. If a pattern of light be displayed on one end, each fibre will transmit the light from a small area of the pattern to the second end and the image will be reassembled

LIGHT GUIDE PRINCIPLE. A ray passing through a curved light guide of circular cross section is internally reflected, as long as the angle (a) on the inside face of the light guide is within the angle of total internal reflection. With a curved light guide, the combined angle (a + b)—where (b) is the angle of curvature—must be within the angle of total reflection. This is usually the case as long as the guide is not curved into a radius of less than about three times its diameter.

IMAGE FORMATION. In a fibre optical system each fibre end picks up and transmits the average light falling on its cross section. A fibre bundle can transmit a picture broken up into image elements corresponding to the fibre elements. (The object is here seen from the front; the fibre bundle however is seen from behind—hence the apparent reversal.)

on that surface. The principle is much the same as that used in television, with the important difference that, because the light from every point of the incident image is transmitted all the time, no storage of energy or scanning device is needed.

Such a bundle of fibres can be very flexible, because the fibres need to be constrained to a definite order only near their ends. With an objective lens on one end and an eyepiece or camera on the other, such a bundle forms an endoscope for inspecting cavities inaccessible in a direct line from outside. Light may be transmitted into the cavity through fibres around the image-transmitting area. Such endoscopes have application to industrial and medical inspection.

Simple bundles are made of fibres between 0.0005 and 0.002 in. in diameter and are capable of resolving up to 20 lines per mm. on their end faces. More elaborate bundles are being developed in which each of these fibres contains a matrix of high refractive index cores surrounded by low refractive index material. With these the resolving power may rise to 100 lines per mm.

Fibre Faceplates. When an image is formed on a phosphor layer inside a cathode-ray tube or image-intensifier, a photographic emulsion cannot be placed in immediate contact with it. Definition is lost because the light spreads sideways in its passage across the thickness of the glass envelope. Lenses can transfer to a film situated elsewhere only a few per cent of the light emitted at all angles by the phosphor. They also add to the length of the whole system.

A mosaic screen of parallel glass fibres (fused together so as to be vacuum-tight, but remaining optically separated by their coatings) therefore replaces the simple glass window. This redisplays the image on the accessible outer surface of the tube, transferring as much as three-quarters of the light from the phosphor.

Such fibre screens can be made with one surface curved to fit the image surface of the electron optics, so acting as field flatteners.

FIELD. With a lens, the extent of the scene in front of it that it is capable of reproducing as an acceptably sharp image. It may be expressed as the angle subtended at the lens by the diameter of the maximum acceptable image circle.

See also: *Covering power.*

FIELD CAMERA. Plate or sheet film camera for commercial and professional photographers, sufficiently portable to be taken on location for field work. The field camera is the forerunner of the modern technical camera, and has many of the adjustments and controls of the latter.

Field cameras were usually made in quarter-plate to whole-plate sizes ($3\frac{1}{4} \times 4\frac{1}{4}$ ins. to $6\frac{1}{2} \times 8\frac{1}{2}$ ins.) Larger formats are no longer portable enough to qualify for consideration as field cameras; they are studio models.

Construction. Most field cameras are made of wood and are of the folding baseboard design. A shallow box-like camera back is hinged to a baseboard. The box is the camera back and takes a focusing screen or plate or film holders. Usually the focusing screen runs in guides and has to be removed before the film or plate holder can be inserted. Frequently the film holder can be inserted in two ways, horizontally or upright.

On some models the carrier for the screen and film holders rotates to permit rapid switching over from horizontal to upright shots, or to arrange the picture format in any intermediate position.

The baseboard carries extending runners rather like a flat bed technical camera to provide a double or sometimes even triple focusing extension. The lens panel moves along these runners and is connected to the camera back by a set of bellows.

In addition to holding the back at right angles to the baseboard, struts usually allow it to be fixed at an angle to the vertical as well. This gives a limited tilting movement about the horizontal axis. Sometimes there is also a lateral swing to bring one side closer to the lens than the other.

The lens panel is hinged to give both lateral and vertical swings and in addition incorporates rising and cross front movements.

The Tripod. The field camera is invariably used on a tripod, so this frequently forms an essential part of it. In some cases the camera baseboard is itself the tripod head, with the legs attached to the baseboard.

The tripod normally consists of collapsible wood or metal legs and tends to be bulky to ensure the necessary rigidity for supporting the appreciable weight of the camera.

Lenses and Shutters. The lens of the field camera is usually interchangeable and mounted on lens panels which clip into the front standard. Focal lengths vary according to the camera format. Field cameras used to be equipped with convertible lenses as well, where two components of a lens unit could either be used together or separately—giving longer focal lengths in the latter case.

On the more modern versions the shutter is built into the lens and changed together with the latter. That means that every lens has its own diaphragm shutter associated with it, which, of course, makes the acquisition of an optical outfit more expensive.

As the older types of field camera were designed for use with slow sensitive materials and time exposures at small apertures, they are not always fitted with shutters. Sometimes the lens cap is considered adequate for controlling the exposure. Alternatively, a variety of shutters attach to the front of the lens (blade or roller blind types) and are then changed over from one lens to the other when the lenses themselves are changed.

Field cameras also exist with behind lens shutters, but generally internal shutters of any kind are rare.

Focusing. The field camera is always focused visually on a ground glass screen fitted in place of the plate holder. The screen holder is so designed that the ground surface lies in the exact plane occupied by the emulsion surface of the plate or film when the latter is in the camera.

Sometimes the ground glass screen carries a clear spot with a reference mark (hairline cross) in the image plane for aerial focusing. This can even be home-made: it involves drawing a cross in pencil in the centre of a ground glass screen, and cementing a small round microscope cover glass over it with Canada balsalm. The latter fills in the ground surface, rendering it completely transparent, while the pencil cross provides the visual indication of the plane in which the image must be focused.

Usually the focusing movement is a rack and pinion mechanism which pushes the lens standard forward or back. On more elaborate field cameras the camera back may be mounted on a separate standard instead of being hinged to the baseboard. In that case the back is also movable on the baseboard.

Scope. For many years the field camera was the standard instrument of the commercial and technical photographer, and has most of the scope—even if not all the convenience—of the modern technical camera. Compared with the latter, the field camera was often more limited in its camera movements and adjustability.

Its main fields of application were landscape photography, architectural and industrial work as well as close-up, medical and scientific photography.

While wooden field cameras are often regarded nowadays as museum pieces, they were made with surprising precision and are still found in the second-hand camera markets.

FIELD CAMERA. Top left: *General view against 1 in. square grid.* Top right: *Front view.* Bottom left: *Side view.* Bottom right: *Rear view with back removed.*

The main features of the camera are: A, *knob for locking movement of back along baseboard.* B, *swing back control, also drops baseboard when required for use with wide-angle lenses.* C, *bracket supporting lens standard.* D, *removable lens panel, carrying lens and shutter, held in position by a sliding ledge at the side.* E, *rising front control; two opposing arrows on the front of the panel indicate when the lens is centred.* F, *shutter speed control (many of the older field cameras have air brake shutters, in which case the speed dial is linked to the air brake cylinder).* G, *knob locking lens panel swing. Two catches on the front of the panel engage when the lens panel is at right angles to the baseboard.* H, *catch to lock movement of lens standard along baseboard.* I, *lens.* J, *baseboard extension.*

FIGURE STUDIES. Photographs of all or part of the human figure, whether clothed or not, in which the interest lies in the impersonal aesthetic values and not—as in full-length portraiture—in the character of the subject.

See also: *Nude photography.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

FILAMENT LAMP

Type of lamp that provides what is perhaps the cheapest and most convenient electric light source. In a filament lamp, electricity passes through a conducting filament and raises its temperature until it becomes incandescent.

Carbon. The first filament lamps were made by Edison and Sir Joseph Wilson Swan who used a carbon filament made by charring a fine thread of organic material. This filament was supported in a glass envelope from which all the air had been extracted. In the absence of air the carbon could be made to glow without burning away. Carbon filament lamps of this kind gave a reddish coloured light and had an efficiency of about 2½ lumens per watt.

Tungsten. Modern filament lamps use a metal filament—generally tungsten—in an inert gas. They are more efficient than carbon filament lamps because they can be run at a higher temperature and so produce more light for a given consumption of electricity. Because the temperature of the tungsten filament is higher, the light it gives is also whiter—i.e. it contains a higher proportion of blue rays than the light from a carbon filament. At the same time, the light given by a tungsten lamp is still unduly rich in red rays when compared with daylight.

The temperature of the filament is nowadays increased by coiling it in a close spiral to reduce the amount of the free radiating surface. A modern gas-filled tungsten filament lamp has an efficiency of about 13 lumens per watt, and a colour temperature of 2,900 degrees Kelvin.

Over-run Tungsten Lamps. The greater the current carried by the filament, the brighter the light it gives and the higher the efficiency of the lamp. But as the working temperature of the filament is raised its life is shortened.

It is standard practice to design the filament of the ordinary domestic lamp to run at a temperature that will give the lamp a life of about 1,000 hours.

There are two types of lamp manufactured for photography, however, in which the filament is run above this economical value. This is done with the object of getting a large amount of light for a comparatively low consumption of electricity. Such lamps are said to be over-run because the same effect can be produced by running an ordinary lamp above its normal voltage and thus making it carry a heavier current. But as the special lamps are designed for the normal mains supply voltage they cannot strictly be termed over-run.

Nitraphot. In this lamp the filament runs at a temperature which gives it an average life of 100 hours. As a result, its output is about twice that of an ordinary lamp of the same rating.

The standard Nitraphot is rated at 500 watts and has a light output equal to a lamp of about double the consumption. This lamp has an efficiency of 17 lumens per watt and a colour temperature of 3,200 degrees Kelvin.

The bulb of a Nitraphot is slightly smaller than that of an ordinary 500 watt lamp and it is fitted with an Edison Screw (E.S.) cap.

TUNGSTEN LAMP FILAMENTS. Left: *Bunched filament of spotlight lamp producing a small source of light.* Centre left: *Open filament of flood and general service lamps.* Centre right and right: *Supported filaments of projection lamps of single or bi-plane construction. The design of the supporting grid depends on the burning position for which the lamp is intended.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Photoflood. This type of lamp is so severely over-run that it has a life of only a few hours, but it gives a very brilliant light in relation to its consumption. There are two sizes in common use.

The No. 1 consumes 275 watts and is equal to a normal lamp of 800 watts. This lamp lasts for about two hours when used intermittently—i.e., when it is never switched on for more than a minute or two at a time.

The No. 2 Photoflood consumes 500 watts and is equal to a normal lamp of 1,600 watts. This lamp lasts for about 7 hours when used intermittently.

Photoflood lamps have an efficiency of about 36 lumens per watt and a colour temperature of 3,400 degrees Kelvin.

Photoflood lamps are popular for amateur still and cine photography indoors because they are cheap to replace and enable comparatively ambitious effects to be achieved with the current from a domestic supply point.

Projection Lamps. Special filament lamps are manufactured for use in conjunction with optical projection systems—e.g., in spot lamps and still or motion picture projectors. These lamps are made as small as possible, and the filament is designed to provide a very compact area which will remain rigidly in focus.

One way of reducing the size of the source is to design the lamp for 110 volts instead of the normal 200–250 volts. Halving the working volts enables the filament to be made proportionately shorter and thicker, which gives a brighter, whiter, and smaller source. Such lamps must be used in conjunction with a voltage-reducing transformer or resistor.

Small, high intensity, lamps of this type tend to run very hot and must have ample—often forced—ventilation. In addition, unless specially designed, they must always be mounted upright or the hot filament may sag out of shape (or one coil may even come into contact with another and cause a short circuit). The working position of projection-type lamps is always marked on the bulb.

Projection lamps generally have pre-focus caps, which are flanged and fitted in such a way that the distance from the filament to the locating flange is the same for all lamps of that type—i.e., so that the light source always lies on the optical axis of the projector.

Integral Reflector Lamps. Lamp reflectors tend to be awkwardly large, add to the weight and cost of the lamp support and quickly tarnish and collect dust. For these reasons external metal reflectors are being replaced by reflectors inside the lamp itself where they stay bright, take up no extra space and add very little to the cost of the lamp.

Where the optical performance does not need to be very precise, as in the photoflood lamps, it is enough to silver part of the inside of the glass bulb. Such photoflood lamps have a modified bulb shape and part of the glass is mirror-coated inside to act as a reflector. This concentrates approximately 75 per cent of the light in a cone with an angle of 60°. Integral reflector lamps of this type are manufactured in the two regular sizes: 275 watts (3 hour life) and 500 watts (10 hour life). The colour temperature is adjusted to suit the A type colour materials.

INTERNAL REFLECTOR LAMPS. Left: The fully silvered bulb has its back blown out to an ellipsoidal reflector and the front to a spherical reflector with only a window for the focused light beam. The spherical front reflector thus utilises virtually all the light from the filament. Right: An internal proximity reflector has a similar function and makes an external mirror in the lighting system unnecessary. Both these lamps concentrate their light into the plane of the transparency or film without the need for separate condensers.

Internal reflector lamps are also coming into increasing use in projectors, especially for cine. Here one of the problems is to get the maximum amount of light concentrated on the area of the gate. Even with a precisely-aligned reflector and condenser system, a good deal of the light spills around the edges of the light collectors or falls uselessly around the target area. Some types of projection lamp therefore use a small, precision reflector mounted inside the lamp and close to the filament. The same result can also be achieved by shaping the projection lamp envelope to act as a reflector, the glass being silvered inside. In this position the reflector intercepts a much higher proportion of the light emitted by the filament and will focus it accurately on the gate. In an 8 mm. or 16 mm. projector this arrangement does not even need a condenser system. Such lamps often also use a low-voltage filament, with a further gain in luminous efficiency. The combined increase in light output is so great that an integral reflector lamp will give a screen brightness equal to an orthodox system of five times the power.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Quartz-Iodine (Tungsten-Iodine) Lamp. One of the reasons for the eventual failure of a gas-filled tungsten lamp is that the filament gradually evaporates (and deposits itself on the inside of the glass envelope) until it breaks. Even before that happens, the shrinking cross section of the filament increases its resistance, cuts down the power and lowers its colour temperature, while the film of tungsten that settles on the inside of the glass reduces the useful light still further.

In the quartz-iodine lamp a small trace of iodine enclosed in the envelope prevents this from happening. When the lamp is switched on, the iodine vaporises and combines with the tungsten deposit on the envelope to form tungsten iodide. This decomposes in contact with the incandescent filament into tungsten, which unites once more with the filament, and free iodine vapour. As a result, the envelope stays clean, the tungsten filament maintains its cross section, lumen output goes up 20 to 30 per cent and the useful life of the lamp is roughly doubled. In addition, the lumen output and colour temperature stay constant throughout the life of the lamp—an important advantage in photographic studio lighting.

The reaction between the iodine vapour and the tungsten deposit on the envelope will only take place if the temperature is above 250°C.

QUARTZ-IODINE LAMPS. Top: 625 watt or 800 watt lamp for use in studio reflectors (approximately two-thirds natural size). Bottom: Quartz-iodine projection lamp, about 1¼ times natural size. Right: 1,500 watt strip form lamp for floodlighting. This is about 10 ins. long.

This is ensured by enclosing the filament in a narrow quartz or high-melting-point glass tube instead of the conventional glass bulb. So a quartz-iodine lamp is very much smaller than a normal tungsten lamp of the same power and can be used with smaller and nearer reflectors. Quartz-iodine lamps for general lighting have a straight tube with a contact at each end.

Quartz-iodine lamps are used for general studio floodlighting in place of ordinary tungsten filament lamps, the units being very much smaller and easier to arrange and store than orthodox floods of the equivalent power.

Quartz-iodine floodlights are available in all the normal voltage ranges from 12 up to 240 and in a range of ratings from 100 to 10,000 watts. The portable lamps of up to 1,000 watts use a short tube and can be operated at any angle without ill effects. The more powerful studio lamps have a longer tube which is apt to blacken at one end if it is worked at more than 4 degrees to the horizontal.

Quartz-iodine photographic floodlights may be of the over-run type. This means that the filament is designed to give an abnormal amount of light at the cost of a much shorter life.

Normal quartz-iodine floodlights—from 1,000 to 10,000 watts—have a guaranteed life of up to 2,000 hours with a luminous efficiency of 22 lumens per watt and a colour temperature of 3,000°K. Quartz-iodine photographic floods —usually below 1,000 watts—have a luminous efficiency of 34 or more lumens per watt and a colour temperature of 3,400°K, but the life drops to 12 hours. Even so, the performance and life of a quartz-iodine photographic flood are greater than for an ordinary photoflood, although the cost is much higher.

This type of lamp is also fitted in the compact, camera-mounted, portable lighting units used for amateur still and cine photography. The small quartz tube requires only a tiny reflector, and a typical 800 watt lamp will give a light equal to three 500 watt reflector photofloods and last twice as long.

As the light source is a horizontal tube, the spread of light is greatest in the horizontal plane and least in the vertical plane. This suits the photographer on most occasions, but for the special jobs that require a greater vertical spread, the lamp unit can be swivelled at right angles. Some types of quartz-iodine lamps are produced as sealed beam units inside specially designed reflectors resembling a motor car headlamp. When the lamp burns out the whole reflector is replaced.

Single-ended quartz iodine lamps are further used in slide and film projectors where the extremely compact type of light source makes it possible to employ a much more efficient optical system. For this purpose the filament is over-run, giving a colour temperature of some 3,300°K. and an efficiency of about 28 lumens per watt with a life of at least 50 hours.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Quartz-iodine lamps run at a much higher temperature than normal tungsten lamps and must be left for as long as 10 minutes to cool down before they can be handled. On switching off, the iodine vapour produces a pink glow and it can be taken that as long as this glow is visible, the lamp will be much too hot to touch.

If the tube of the lamp is touched with greasy fingers when it is cold, the marks will produce opaque black spots when it heats up. These can be cleaned off with methylated spirit but it is wiser to polish the tube clean with a dry rag before use if it has been handled at all. F.P.

FILING NEGATIVES AND PRINTS

Any filing system for negatives should serve two main purposes. Firstly, it has to hold the negatives themselves together with the relevant technical and other data and, secondly, it should allow any negative to be found at a moment's notice.

Every serious photographer should, therefore, have a storage system for negatives and data (probably including a contact print for identification) and an indexing system. Both must allow for indefinite expansion. There must always be room for more without having to reclassify the system.

Storing Negatives. The basis of the storage system for negatives will be negative albums. Often it is most practical to make such an album from transparent or translucent envelopes, punched along one side so that they can be inserted into a loose leaf binder. Or it may be found more convenient to stick a narrow strip of paper to one edge of each envelope and punch this.

The envelopes are numbered, and the negatives are inserted in the order in which they were exposed. For additional safety it may be as well to write the number of the negative on the margin of the film with a very fine pen. Some photographers even add their names.

This will do for single film negatives of most conventional sizes. 35 mm. negatives are best stored in lengths of four or six exposures in envelopes of suitable size and shape. The envelopes containing a strip can still be numbered consecutively, while each negative receives the envelope number and suffix. Thus envelope No. 485 would contain negatives 485a, 485b, 485c, and so on.

Plates are best kept in special plate boxes which are grooved to keep each plate separate, and the grooves are numbered.

Where there are several negative sizes which will not go into one type of album, they may be accommodated in several albums and have the negatives numbered separately in each. The numbers will be preceded by a letter, so that, say, all the numbers from A1 onwards will be 35 mm. negatives, from B1 onwards V.P., 2¼ × 2¼ ins. and 2¼ × 3¼ ins. films, and the series beginning with C1 may be half-plate glass negatives.

Photographers who specialize in one particular subject can start a series D1—e.g., for portraits—or go further and subdivide and use double prefixes.

But although some people are quite at home in a complicated system of this sort, others find it very confusing. Anyone who finds such a system confusing should make negative numbers depend on their size and chronological order only.

As an alternative to making the envelopes up into a negative album, they can simply be kept loose, in their numerical order, in boxes.

Negative Data. Most negative albums have no adequate provision for entering exposure and other details. Therefore these should be entered separately on data sheets.

The data are the usual details about subject, location, aperture, shutter speed, time of day or other illumination data, sensitive material, filters, date, and development.

Each data sheet carries the same number as the corresponding negative, and has a contact print attached to it. With several negative sizes the tidiest plan is to make an enlargement of the whole of every negative so that all the prints are the same size (which will depend on the largest negative size). The prints need not be technically perfect, as they serve mainly for identification. On the prints should be written details of where shading or overprinting is needed during enlargement, and what parts of the negative are to be used.

Further details to go on the data sheets are: the most suitable grade of enlarging paper, whether and where the picture has been submitted, published, sold, etc.

A typical layout for a data sheet may look something like this:—

DATA SHEET

Neg. Number..... Roll..... Exp. No.....

Contact print or standard size enlargement

Subject .....
Exp..... sec., *f*.....
Plate/ film .....
Lighting .....
Time of day..... Date.....
Filter..... Camera.....
Lens..... cm./in., *f*.....
Developer .....
min. at .....°F./°C.
After-treatment .....
Suitable printing paper.....
Notes .....
.....

Indexing. These data sheets can serve as their own index. The most straightforward method

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

is to file them under subject headings arranged alphabetically in a loose leaf book. Thus there will be headings like Children, Portraits, Industrial, etc., with the data sheets inserted under them in numerical order.

If the number of sheets under any heading becomes too great for convenient handling, it will be necessary to subdivide the headings. Portraits can be subdivided into the names of sitters (arranged alphabetically). Travel into geographical regions and place names, and so on.

An index also needs extensive cross-references. These can be dealt with by preparing several data sheets of the same negative where required, and inserting them under the several appropriate headings. To save time and materials, blank sheets should be inserted under the alternative headings. These sheets will only bear the negative number or numbers, and a reference where the data sheet is to be found. For instance, under Table Top there might be a sheet marked: "C255, C256, A327, A335—see Advertising Photos."

In this way the indexing can be made independent of the storage system. The negative numbers only identify the negatives, and the two systems are self-contained. To use the index look up the subject and subdivision, run through the sheets there to find the required picture, note the negative number and then take the corresponding negative out of the file or box. This is the only occasion when the negatives themselves are handled.

An alternative method of filing negatives makes use of a card index. Each negative is stored separately in an envelope as before (or strips of four or six negatives to one envelope in the case of 35 mm. film). Each envelope is then stuck on the back of a card.

This system needs a separate index, which can also be a card index, or else a loose leaf binder. However, instead of data sheets there is one sheet or card for each subject. On this all the relevant negative numbers are entered. No subdivisions are used; the sheets are simply labelled like the index in a book. Thus when the sheet Villages becomes too full for easy reference, it is replaced by several sheets: Villages—Kent, Villages—Sussex, Villages—Wales, etc.

The Decimal System. There is yet another system, which can be adapted for photographic filing and applied to data sheets and cards.

The subjects are divided into not more than ten groups, each covering as broad a field as possible. The groups are assigned single key numbers from 0 to 9—e.g., 0 for Portraits, 1 for Sports, 2 for Travel, etc.

Each group is then subdivided, and each subdivision given a second key number. Thus, under Travel, 21 might mean Europe, 22: Asia, 23: North America, etc.

Further subdivision produces 211: British Isles, 212: Western Europe, 213: Central Europe, 214: Scandinavia, etc., while the next stage would be 2121: Holland, 2122: Belgium, 2123: France, etc.

A key list of these numbers is prepared to show which key and subsidiary key numbers refer to which classifications. It is also necessary to prepare an index card or sheet for each negative, bearing the negative number and classification number. If several negatives fall into the same category, they all come on to one index card. If any card becomes too full, it is replaced by a number of new ones, carrying the division a stage farther.

Some negatives may occur on several index cards under different classification numbers. Thus St. Paul's Cathedral would fit into both 2114 (Travel — Europe — British Isles — London), and 5413 (Architecture—Church Buildings—Cathedrals—Seventeenth Century).

Instead of index cards the data sheets of the negatives can be used. The classification number is written on them in addition to the negative number. Entries under alternative headings are dealt with by blank sheets bearing only the two numbers.

The index cards or data sheets are kept in numerical order according to their classification numbers, and not by the negative numbers. The order of the classification numbers depends on the actual digits, from left to right, and not on the length or numerical value of the complete number. Thus 4216 would come before 638, not after.

To find a negative of any subject: look up the subject classification in the key list, find the corresponding index card or sheet, and get the negative number from it, take out the corresponding negative from the album or file.

Print Records. A processing record of every print made enables identical further prints to be made at a later date.

The method is simple. Before each piece of bromide paper is exposed in the enlarger, it is numbered on the back with a soft pencil using very slight pressure to avoid pressure marks on the face of the print. The pencil marks will not wash off during normal processing, and when the print is finished the reference numbers can be gone over with Indian ink or a rubber stamp for greater permanence.

For the actual records it is convenient to use a large note-book ruled in columns. As each print is made, the following details are entered in the book: print number, negative number, paper type and grade (usually the manufacturer's code number will do for this), the maker's batch number, and the exact degree of enlargement.

If the enlarger column is marked in inches or centimetres, it is easy to note the height of a convenient part of the lamphouse above the baseboard. All enlargements with the lamphouse in this position will have the same degree of enlargement. Otherwise to get the exact

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

degree of enlargement it is necessary to measure the exact width of the negative in the negative carrier—or draw or scratch two lines a fixed distance apart on an unimportant part of the negative—and to measure the corresponding size of the image of these two lines on the baseboard.

Further details required are: focal length of enlarging lens (only if there are several lenses for different negative sizes), aperture, exposure time, developer, shading or other control, print size, after-treatment, and a column for any other notes (what the print is used for etc.). If a photometer is used for determining exposures, there should also be a column for the photometer readings.

To make a duplicate of any print, it is only necessary to look up the print number in the record book, select the paper, set the enlarger and expose, etc., as indicated.

Print Files. The print files are much simpler, as prints will be taken out as well as put in. The files will consist of the finished prints on hand before submitting them to journals or papers.

The prints are sorted out according to subjects, and put into large envelopes (about 8 × 10 ins. to accommodate the largest print likely to be used) or boxes, with the name of the subject written on the outside. Containers are filed alphabetically. If a print comes under several headings, it is filed under the most appropriate. A sheet of paper with a note—e.g., See also print No. XX, Churches—as applicable, is filed under the alternative subjects. It is best to stick to this method even if there are several prints from the same negative, rather than to distribute them in various containers. The prints are then all in one place, and a check can be kept on how many prints there are from one negative in stock.

It is also possible to use the decimal system already described for prints using the same key list as for the negatives. The prints have the classification numbers put on the back, and are stored in the order of these numbers. Alternative classifications are dealt with as before by blank sheets with appropriate cross-references. If possible, it is best to avoid overlapping classifications.

There is no need to go to a very elaborate system, as the quantities in stock are much more likely to be easily manageable than the negative files. If, however, there are too many, it is satisfactory to store them in the order of their negative numbers and use the negative indexing system to find a print of any particular subject.

All prints should be numbered with the negative number as well as with the print number, so that reference can be made to the negative files and processing records for all technical details.

Prints Sent Out. It is essential to keep a record of all prints submitted for publication.

For this a loose leaf book will serve, devoting a sheet to each negative number from which prints have been sent out. The sheets are inserted in numerical order.

On each sheet is entered the date when a print was submitted, its number, where it was sent, when it was accepted (or returned), published, the size of the published picture, and when it was paid for (including amount received).

If several prints are sent out, these details are noted about every one of them. It is also necessary to state whether the negative or copyright is sold, or if the prints have been submitted through an agent. If a contact print from the negative is stuck on each sheet, there is no need to refer back to the negative file to identify the print.

This record also needs two indexes. In the subject index under each heading is entered the negative from which prints have been submitted, accepted, or rejected, and also where they were submitted. This subject index can also be based on the decimal system as for negatives.

The second index is one of magazines and papers to which pictures have been submitted. Under each paper is entered the negative number, subject, date of submission, and publication.

With these two indexes it is possible to see at a glance what markets have been covered with which subjects.

Storing Transparencies. Transparencies comprise lantern slides, film slides (film transparencies bound between glass), unbound transparencies, and film strips. These may be either black and white or colour.

Slides and film slides may be stored loose in boxes, with the slides numbered for index reference. Each box may hold about 50–100 slides. Special slides boxes are made which hold the slides in separate grooves for easy access and sometimes have a carrying handle for portability. Large collections can be stored in drawer cabinets made up of such boxes.

Unbound transparencies, especially in colour, are best kept in transparent envelopes; this permits viewing without risk of damage. Film strips are stored rolled up in cardboard or metal tins.

Indexing Transparencies. Any of the indexing systems for negatives and prints can be used, according to the size of the collection and needs of the owner.

Advanced systems like detailed subject subdivisions or the decimal classification will prove most useful when the transparencies are required for a stock file for publication. In that case it is best to have separate files for unique transparencies (e.g., original colour transparencies produced in the camera on reversal film), and for duplicates or positives printed from an original or negative. The former would then be indexed like a negative file and the

latter like a print file with references to the originals or negatives.

Slides illustrating a lecture are best kept together as sets, though individual numbering will enable them to be referred to in the common index with other transparencies whenever an individual slide is required.

With film strips a set is joined together

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

can be filed by subject.

It is absolutely vital for a filing system, once started, to be kept up to date. There are no half measures: it is either complete and accurate, or it is useless.

L.A.M.

Book: *Camera Copying and Reproduction*, by O. R. Croy (London).

FILL-IN LIGHT. Any light directed on to the subject from a lamp or reflector to illuminate shadows cast by the principal light on the subject. Without some such form of shadow illumination, those parts of the subject not lighted by the principal light would appear in the finished photograph as dense black areas with little detail.

For normal subject lighting, the power of the fill-in illumination of the shadow areas is usually one-third of that given by the principal lighting.

See also: *Against the light; Flash technique; Lighting the subject; Portraiture.*

FILM CLIP. Metal (usually stainless steel) or plastic clip attached to the ends of roll films so that they can be hung up to dry. The clip for the top end hangs by a hole or a hook and the lower clip may be weighted to keep the film taut. As the ends of a wet film are slippery, the jaws of film clips are spiked or serrated and held closed by a strong spring. A normal type of clip—e.g., a bulldog paper clip—is apt to slip and the film must be handled specially carefully when dipped in.

Metal film clips should always be made of rustproof material.

See also: *Developing negatives.*

FILM COUNTER. Counting mechanism in many modern cameras, especially 35 mm. models, which shows the number of exposures already made on a length of film, or the number of frames still available.

See also: *Film transport; Miniature camera.*

FILMING. Term broadly covering all the activities of making motion picture films with narrow gauge (including amateur) and standard cine camera.

See also: *Cine camera; Cinematography; Cine techniques; Editing; Projection practice; Projector (cine).*

FILM PACK. Standard form of pack in which negative material may be bought. It consists of a number (usually twelve) of separate sections of film assembled in such a way that they can be exposed singly in an adaptor fitted in place of the plate holder of a plate camera and removed singly for processing. Film pack material is generally rather more flimsy than cut film and should therefore be processed in a dish, as the cut film holders for tank development are not suitable.

See also: *Film transport.*

FILMS. Sensitized materials in the form of an emulsion coated on a flexible base—e.g., celluloid or plastic. Films for still photography are available in four standard forms: roll films, perforated film, sheet film and film packs.

History. Long before the introduction of celluloid film, attempts were made to replace glass plates by a less heavy and fragile support.

Stripping film, which could be peeled off the glass plate, was mentioned by Frederick Scott Archer in his communication of the collodion process in March 1851. Other methods of stripping the negative from its glass or paper support were put forward by Alexander Parkes (1856), C. M. Ferrier (1857), Leon Warnerke (1875), Thiébault (1883), Georges Balagny (1883). George Eastman introduced stripping film for use in the Eastman/Walker roller-slide in 1886.

Flexible sheet film needing no support was patented by Alexander Parkes in 1856. Though his film of several layers of plain collodion never found application, with this idea Parkes laid the foundation for many flexible film supports which were devised mostly in the 1880s, the most important of which was celluloid, a material invented by Parkes in 1861. Various films of gelatine and/or collodion were devised by H. J. Palmer and F. Wilde (1878), Ferrier (1880), E. Stebbing (1881), Alfred Pumphrey (1881) and others. Celluloid film was first manufactured in thin (1/100 in.) clear sheets for John Carbutt, an English photographer in Philadelphia, who in 1888 introduced emulsion-coated celluloid sheet film.

The Rev. Hannibal Goodwin of Newark applied for a patent on 2 May 1887 for a very thin transparent rollfilm made of celluloid, which was not granted until 1898. Meanwhile the Eastman Company had captured the market with a similar rollfilm patented by their employee H. M. Reichenbach, 1889. This eventually led to a lawsuit lasting twelve years; in 1914 the Eastman Kodak Co., who by that time had a virtual world monopoly in rollfilms, settled with the Ansco Co.—owners of Goodwin's patent—for five million dollars.

With this transparent rollfilm invented by Goodwin and popularized by George Eastman, the modern era of photography began, the only

CC-0. Agamnigam Digital Preservation Foundation

change being the replacement of inflammable celluloid by non-inflammable cellulose acetate about 1930. H. & A.G.

Roll Films. These are mounted on a numbered opaque paper backing and wrapped on a wood or metal spool. The commonest size is 2½ ins. wide film which yields eight pictures measuring 2¼ × 3¼ ins., twelve pictures 2¼ × 2¼ ins. or sixteen pictures 1⅝ × 2¼ ins., according to the camera.

Perforated Film. The original film used in 35 mm. miniature cameras was simply standard 35 mm. cine negative film. Nowadays perforated 35 mm. film is manufactured specially for still cameras. It differs from the cine film in a number of respects—in particular in the type of coating. The perforations enable the film to be moved exactly one frame at a time by the film transport mechanism, thus eliminating the numbered paper backing. The standard picture size for cameras taking perforated 35 mm. film is 24 × 36 mm.; a number of cameras use smaller formats such as 18 × 24 mm. (half-frame) or 24 × 24 mm. Perforated film in larger sizes is used in special scientific and technical photography—e.g., in aerial survey and instrument recording cameras, as well as for document recording. Established standard widths there are 70 mm. and 105 mm.

Perforated 70 mm. film is also becoming popular for professional and technical cameras and even special roll film cameras. The film yields pictures 2¼ ins. wide ty 2¼ to 2⅞ ins. long (according to camera) and is usually packed in cassettes holding up to 15 feet of film.

Certain hybrids between roll film and perforated film—a kind of perforated roll film—also exist for special cameras. In one case the film is rolled up in special cassettes together with a backing paper, and a perforation (one per picture frame) serves to arrest the transport movement of the camera rather than to advance the film directly.

Perforated and unperforated 16 mm. film is used in sub-miniature or ultra miniature cameras yielding pictures from 10 × 14 mm. to 12 × 17 mm. The film is usually packed in single (sometimes double) cassettes without a backing paper. Either the film perforation or a gearing with the take-up spool of the cassette serves to advance the film. One camera even uses unperforated 9.5. mm. film.

Sheet Film. This, known also as flat film and cut film, is manufactured in all normal plate negative sizes. The base is thicker than that used for roll films and there is no paper backing. Sheet film is loaded into special film holders which hold the film flat and in the correct focal plane in the camera. Sheet films can also be loaded into plate holders in the same way as a plate, but a piece of black card of the same size as the film must be placed behind it to make up the thickness. Film sheaths are also available to hold sheet film in plate holders; these are flat pieces of metal with grooves to hold the film in place, and go into the plate holder in the same way as a glass plate.

As there is very little difference between the feel of the back and the front of sheet film, it is notched in manufacture so that the emulsion side can be identified. When the film is held with the long side vertical and the notches are at the right hand end of the top edge, the emulsion surface is facing towards the operator.

Film Packs. A film pack is a convenient package of twelve pieces of cut film attached to paper separators with numbered tabs in such a way that each film in turn can be brought into position for exposure in the camera. This method of packing has the advantage of allowing individual films to be extracted and processed without waiting for the whole pack to be exposed. Film packs are now virtually obsolescent; they were always more expensive exposure than the equivalent size in sheet film.

The film pack is exposed in a special film pack adapter which fits into the plate holder grooves in the back of a plate camera.

Cine Films. The sensitized materials used in cinematography are normally available in four gauges: 8 mm., 9·5 mm., 16 mm., and 35 mm.; for special techniques, such as wide screen projection, larger gauges such as 65 mm. are used.

Cine films are perforated down one or both sides. The size and number of perforations depends on the type of film and gauge.

Spools, magazines or cassettes are employed for loading cine film into the camera.

See also: *Cine film; Colour materials; Film transport; Negative materials; Perforation; Reversal materials; Sizes and packings; Supports for emulsions; Transparency materials.*

FILM SETTING. Method of assembling printed texts etc. on a film by printing individual letters from appropriate negatives. The film carrying the completed text is then used for making a printing plate by photo-mechanical means. In film setting machines the selection of the letter negatives and their alignment, exposure of the film etc., proceed automatically at high speed, being controlled by a keyboard somewhat like a typewriter keyboard.

See also: *Photomechanical reproduction; Photo-typesetting.*

FILM STORAGE. Sensitized materials gradually deteriorate from the moment of manufacure. This deterioration usually involves loss of speed, change of contrast, increase of background fog and—in the case of colour materials—a change of colour balance. Manufacturers therefore mark film cartons and packages with an expiry date (usually about two years from the date of coating) during which time they guarantee the specified characteristics of the film under proper conditions of storage. In practice films may remain serviceable for a considerably longer time.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The storage conditions naturally influence the keeping qualities of the film. Particularly harmful are—in order of importance—radio-activity and harmful radiations (of importance in atomic energy establishments and radio-graphic departments of hospitals), fumes, high humidity and high temperatures.

Storage Conditions. Ideally films should be stored in a cool, dry and adequately ventilated place free from radio-activity, and industrial solvents and vapours (formaldehyde, hydrogen sulphide, sulphur dioxide, motor exhaust gases, ammonia, mercury vapour, turpentine and other solvent vapours). The ideal temperature is 40 to 50° F (4 to 10° C) and the ideal relative humidity 40 to 60 per cent.

Tropical Storage. Manufacturers are increas-ingly going over to packing films in sealed metal foil or plastic wrappings—originally used for materials intended for tropical climates. Such wrappings effectively protect the film against all outside influences (apart from temperature) as long as the wrapping is unopened.

While the film is in such hermetically sealed wrappings, it can also be kept in a refrigerator for longer storage life. This is desirable in hot weather and climates, especially if the film stock must retain consistent characteristics for some time. (For example in documentary coverage with colour film, where large amounts of film of the same batch number are obtained.)

Films stored in a refrigerator must be allowed to reach the prevailing temperature again before the package is opened; otherwise mois-ture may condense on the cold film and ruin it. For the same reason open film (once taken out of its sealed package) must not be replaced in the refrigerator. Once the package is unsealed, the film is best stored in a metal box containing a dehydrating agent (e.g. activated silica gel) to provide a dry atmosphere. Preferably films should be exposed and processed within a few hours of loading into the camera.

In tropical climates moulds are also liable to attack the film when in the camera.

Processed Films. Negatives and coloured trans-parencies should be stored in a reasonably cool and dry place, as far as possible away from fumes such as hydrogen sulphide, etc. Exces-sively warm and excessively dry conditions may render the film brittle; with cine films stored in cans it is usually desirable to have a humidifier pad inside the can to keep the film supple.

In the tropics the greatest danger is attack from insects, bacteria and moulds. Films are best kept in envelopes (preferably treated with fungicide) with a closing flap. Periodic inspec-tion is desirable.

Storage Regulations. Modern cellulose acetate and polyester films present no special fire risk. The old-fashioned cellulose nitrate films however were highly inflammable and subject to special regulations for storage (in accordance with the Factory and Workshops Acts in Britain, and corresponding regulations in other countries). These regulations limit the quantity of nitrate film that can be stored in a single cupboard or drawer, and also specify the type of building required.

Cellulose nitrate films are only likely to exist in old files and motion picture stores; in view of the risks and special regulations, organizations holding such stocks are gradually preparing duplicate negatives or transparencies on safety-base films. L.A.M.

See also: *Keeping qualities of materials.*

FILM STRIPS

A film strip is a series of positive trans-parencies printed on a single strip of 35 mm. perforated film. Film strips may be viewed in a transparency viewer, but they are primarily intended for projection.

A film strip offers a convenient method for showing a number of pictures which have some common link—e.g., the illustrations for a lantern lecture, a series of pictures to advertise a manufacturer's product, or a planned, step-by-step educational sequence accompanied by either a recorded talk, or a set commentary read by the teacher or instructor. Many manufacturers equip their representatives with portable projectors.

Film Strip Printers. The positive prints are made either by contact or projection on to special perforated or unperforated 35 mm. film coated with a slow bromide emulsion of medium contrast. They may also be made directly on to reversal material in the camera although this method is only worth while in special circumstances.

It is usual to make contact prints from 35 mm. negatives for reference only; serious film strips are almost always made by projection printing because it permits more control of the picture and allows strips to be made by reduction from negatives larger than 35 mm.

Contact printers are usually in the form of a frame similar to the body of a 35 mm. camera with the lens panel removed. The spool chambers are big enough to hold at least five feet of positive film, and the picture aperture can be masked for single or double frames. A hinged gate over the picture aperture holds any selected negative in position for printing. After exposure the winding knob automatically advances the positive film to the next frame. The printing light may be an ordinary electric light bulb suspended above the printing table and connected through a dimming resistance for controlling the brilliance.

There are also semi-automatic printers for turning out numbers of film strips from the same copy negative.

CC-0. Adamrigam Digital Presevation Foundation, Chandigarh

Projection printers are necessarily more complicated than contact printers because they must allow for the separate adjustment and refocusing of each new negative. In this case the film holder is generally mounted on a slide on which there is also a focusing stage. The white surface of the focusing stage is at exactly the same height from the carrier as the surface of the emulsion in the gate of the film holder.

The image is focused on the stage with the slide at one end of the track. It is then moved to the other end, bringing the film gate into the exact position previously occupied by the focusing stage. This system allows the negative frames to be printed in any order, or orientation and with any individual degree of magnification.

A 35 mm. camera can also be used as a projection printer by loading it with positive film and fitting an extension tube to give 1:1 reproduction. The film to be printed is held flat in a negative carrier over a cut-out aperture in the top of a box. The light from a lamp inside the box diffused by a sheet of opal glass illuminates the negative and provides the printing light. The camera is held on a copying stand at the correct height over the negative and the exposure is made with the camera shutter.

Special close-up gear of this kind exists for a number of miniature cameras. It usually consists of suitable extension tubes and/or supplementary lenses, together with a copying stand or distance gauge that automatically supports the camera at the right distance from the negative (or transparency). The latter then only has to be placed on top of a light box.

Printing Technique. Film strips must be planned as a whole because they are printed on one continuous length of film. Once printed, the order can only be changed by cutting and splicing the film, which is rarely desirable nor always practicable. Otherwise the whole strip must be reprinted.

The same positive material is used for the whole strip, so the negatives must all be of similar contrast. This is easy enough where film strips are printed from a set of negatives specially prepared for the purpose. For convenience, the negatives should be in the correct order, and all of the same size. When taken on miniature film, the negative film itself can be processed to produce a direct reversal positive film strip.

There are four principal steps in printing a film strip:

(1) Selecting the negatives and arranging them in the order in which they are to appear on the strip. This includes negatives of titles and captions.

(2) Making test exposures to find the exposure time for each negative. A careful note is taken of the exposure time, and amount of magnification or reduction to be used for each negative.

FILM STRIP PRINTING. 1. Select negatives and place in correct order for final sequence of images on strip. 2. Prepare titles and copy them by photographing (preferably on same size of negatives as used for rest of strip). 3. Make test exposures for each negative and note down exposure times in sequence. 4. Print the negatives on to the strip in their final order. 5. Process, wash, and dry the exposed positive strip.

(3) Printing the negatives in their correct sequence.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

(4) Processing the complete strip (usually in a tank).

Orientation of Images. Film strips that have been printed by contact or in the enlarger in the normal way appear the right way round when viewed from the emulsion side: so the emulsion side must face the condenser of the projector when the strip is projected.

Film strips produced by reversal appear the right way round when viewed from the back of the film. So in this case the emulsion side must face the projector lens when showing the strip.

The emulsion side can be arranged to face the lens for a normal strip, if the negative is reversed left to right in the enlarger when printing. But it is not advisable to reverse the negative in this way when contact printing because the emulsion layers of negative and positive material should be in contact with each other; the presence of the film base between the two surfaces would result in some loss of sharpness in the print.

Arrangement of Images. If all the images of the strip face the same way, arrangement is simple. Where a strip contains double (24 x 36 mm.) frames as well as single (18 x 24 mm.) frames, the single frames are always printed in pairs.

Where the strip contains horizontal and vertical single and double frames, the work of the projectionist is made easier if the frames are printed so that the film strip holder needs only to be rotated through 90° when passing from one type of frame to any other. Some projectors may permit a 90° movement.

Thus all vertical double frames and horizontal single frames (vertical strip) should be printed facing one way, and follow underneath each other when the images are viewed the right way round. All horizontal double, and vertical single, frames (horizontal strip) should also be printed facing in one direction, following each other from left to right when the strip is looked at the right way up and the right way round.

The standard type of strip has a blank 9 ins. leader, with a frame marked "start" before the first frame of the strip, and it finishes with a frame marked "end", and a blank 9 ins. trailer.

Processing. It is not practicable to process individual frames separately, and the whole strip is best processed in a developing tank in the same way as 35 mm. film. Such tanks take time to fill and empty in the usual way, and as development times are short, it is wise to fill the tank with the developer first and then immerse the reel in it; this is better than pouring the developer into the tank after the

ORIENTATION OF IMAGES. **Left:** *To permit continuous projection without rotating the film carrier all images must be oriented in the same way on the strip. Possible arrangements are:* A, *vertical double frames;* B, *horizontal single frames;* C, *vertical double frames and pairs of horizontal single frames mixed;* D, *horizontal double frames;* E, *vertical single frames;* F, *horizontal double frames and pairs of vertical single frames mixed.* **Right:** *Correct orientation of images of mixed direction for minimum rotation of film carrier during projection. All images face in only two directions on the strip, irrespective of format.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

reel is there. After development the reel is lifted out in the darkroom and immersed in a dish containing the rinse or stop bath. The tank is meanwhile emptied and the fixer poured in. The reel is then replaced in the tank for fixing and subsequent washing.

The temperature should be constant between developer and rinse, and between rinse and fixer. An acid hardening fixer is advisable.

Single test exposures can be treated like small prints and developed in a dish.

All processing of the sensitive film strip should be carried out by the light of an orange safelight of the type used for bromide paper.

Projection. Film strips are projected in suitably adapted miniature projectors. These incorporate a film strip holder—which may be interchangeable with a slide holder—with feed and take-up spools to take film strips up to 10 feet in length. The individual frames are brought into position by turning the spool knobs and the film is held flat in the gate by a pressure plate. The whole holder rotates through 90° or 360° (according to the model) to project upright and horizontal frames. Better quality projectors include some means of releasing the pressure plate during film transport so as to reduce the risk of scratches, and may also feature interchangeable gate masks for screening 18 × 24 mm. as well as 24 × 36 mm. frames.

Commercial Film Strip Production. The general principles of printing film strips commercially are similar to those of amateur production as described. The equipment and procedure are, however, different, since the amateur methods would be too slow and uneconomical.

Commercial practice generally utilizes semi-automatic or automatic printing machines and continuous processing units of the type employed in motion picture laboratories. The negative for a commercial film strip may be passed through the printer over and over again in a closed loop, or else a number of negative strips joined end to end to print a whole film strip series in one run.

FILM STRIPS BY COPYING. A miniature camera with a 1 : 1 extension tube and distance gauge can copy 35 mm. negatives (or transparencies) directly over a light box.

Availability and Uses. The increasing interest in the use of visual aids in education has made the film strip very popular in recent years. There are now numerous firms who specialize in the making of film strips, and most of these publish catalogues.

Many photographic organizations also provide some kind of film strip service, usually in the form of a free lending library. Film strips covering both technical and pictorial aspects of photography are available, nearly always supplemented with a scripted commentary. More recently, particularly in the U.S.A., film strips have also been issued with tape recorded commentaries to accompany them.

A number of film strip projectors exist combined with a built-in gramophone record player. The strips are then issued complete with a pre-recorded disc. This is more practical with film strips than, for instance, with slide sets, since the strip already carries the images permanently connected.

Other sources of film strips are the publicity departments of major industrial concerns, government bodies and public services.

Film Strips in Colour. Sets of colour illustrations such as paintings and the like, can be turned into colour film strip series by direct photography in a miniature camera on reversal colour film. Since paintings (but also miniatures, objets d'art, etc.) are best photographed by artificial light for maximum control of exposure conditions, an artificial light type colour film is required. The exposures should—as far as possible—be the same (determined after preliminary tests). Where mixed horizontal and vertical views are used, be sure to turn the camera round to only one vertical position, corresponding to the proper orientation of a mixed film strip (see above).

The subject distances (and hence magnifications) can of course vary according to the size of the original. The colour reproduction is also liable to vary somewhat from a true rendering; colour films are rarely able to reproduce artificial pigments with absolute fidelity. In principle a colour negative film can also be used, for printing the positive on to a transparency film. This enables a number of strips to be made of the same negative strip. On the other hand printing control is more difficult and colour negatives contact printed on to positive colour film are liable to lose sharpness owing to the number of emulsion layers involved. Projection printing gives better results. A colour duplicating film can also be used where many copies of this strip are subsequently required.

Film strips can also be made from a set of colour slides. This calls for an inter-negative film or a soft gradation transparency duplicating film. The first yields colour negatives

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

which again have to be printed on to a positive film. The second yields direct colour transparencies with only a comparatively slight loss of colour saturation and tone gradation. (Ordinary colour reversal films invariably yield duplicates of excessive contrast and degraded colours.)

Commercial filmstrips in colour are also available; some outstanding examples deal with well known paintings.

FILM TRANSPORT

Any camera which takes sensitive material in pre-packed loads for a number of exposures must have an accurate, simple and foolproof method of replacing an exposed piece of film in the image plane by an unexposed one. In roll film and 35 mm. cameras this involves winding the film on through an appropriate length corresponding to the space taken up on the film by the image. The transport system has to provide for the smooth advance of the film, give an indication of the amount of film advanced, and show the number of exposures of the load already used up.

The design of the transport system depends on the kind of material employed—roll film, perforated 35 mm. or other film, and so on.

ROLL FILM CAMERAS

On inexpensive roll film cameras (also on most older models) the film transport consists simply of a knob on a shaft which engages the take-up spool inside the camera. The beginning of the film is attached to this spool during loading. The degree to which the film has to be advanced from picture to picture is established by the numbering on the backing paper of the film, and observed through a window in the back of the camera.

Backing Paper. Roll films are backed with an opaque paper strip which carries numbers corresponding to the number of negative spaces on the film. The backing paper is a little wider than the film and extends beyond it at each end. The leading end of the film is attached to the backing paper by a piece of adhesive tape, and there is enough spare paper ahead of it to attach to the take-up spool in daylight without exposing the end of the film.

As the backing paper is wound on to the take-up spool the first thing that is seen through the safe-window in the back of the camera is the outline of a hand. This indicates that the end of the film is just about to enter the negative area. From this point onwards it is not safe to open the camera or release the shutter.

After the hand there may be a series of warning dots followed at last by the figure (1). This indicates that the film is now in position for the first exposure. As each exposure is made, the film is wound on to the next number. When the last frame has been exposed, the film is wound completely on to the take-up spool, leaving its own spool empty and ready to transfer to the take-up chamber.

The backing paper is commonly either black paper with a red or yellow back and black figures, or black paper with a green back and white figures. The safe window in the back of the camera may be either red or green. At one time it was usual to buy orthochromatic film on red backing paper, and panchromatic on green. Red windows were used for orthochromatic films and green windows were either substituted for the red or stuck over the top when a panchromatic film was in the camera. Experience seems to show, however, that the paper backing is in any case so completely opaque that it does not matter what colour paper or window is used. But it is always unsafe to let the direct light of the sun shine on the safe window for more than a second or two.

Roll Film Formats. The most popular roll film size—2½ ins. (6 cm.) wide—has the backing

BACKING PAPER NUMBERS. The backing paper of practically all roll films carries a series of numbers to show how far the film must be wound on to the next exposure. The numbers are observed through the red window in the camera back. Films yielding various numbers of exposures of alternative sizes (e.g., 120 or 620 film) carry several sets of numbers.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FILM WINDOWS. The positions of the windows in the back of a roll film camera are laid down by a British Standard, and correspond to the location of the numbers on the backing paper of the film. Two-size cameras have the appropriate two film windows. The arrows indicate the direction of film travel, the shaded areas the alternative smaller picture sizes. On most modern roll film cameras a shutter keeps the film window closed to protect it against strong light, except when the film is actually being wound on. Left: Size 120 and 620 film for 8 exposures 2¼ × 3¼ ins. or 12 exposures 2¼ × 2¼ ins., or 16 exposures 1⅝ × 2¼ ins. Right: Size 127 film for 8 exposures 2¼ × 2½ ins. or 12 exposures 1⅝ × 1⅝ ins. Some cameras take 16 exposures 1⅛ × 1⅝ ins.

paper numbered down the left edge to give 8 exposures to the roll, down the centre to give 12 exposures and down the right edge to give 16 exposures. So the position of the safety window in the back of the camera indicates the format of the picture. When the window is at the left side the camera takes the oblong format—2¼ × 3¼ ins. (6 × 9 cm.). When the window is in the centre, the camera takes the square format—2¼ × 2¼ ins. (6 × 6 cm.); and with the window at the right the camera takes the 16-on size—i.e., 1⅝ × 2¼ ins. (4·5 × 6 cm.). As an alternative to the right-hand window, older cameras or adapters that take these half sizes have two safety windows. Each number on the backing paper appears twice—once behind each window—and an exposure is made with it in each position. In this way 16 exposures are made on the normal 8-exposure film.

The backing paper for 1¾ ins. (4·5 cm.) wide film is numbered down the centre for the oblong 1⅝ × 2½ ins. (4 × 6·5 cm.) format of 8 exposures and down the left hand edge for the square 1⅝ × 1⅝ ins. (4 × 4 cm.) size. The film windows in the back of the cameras taking this film size are positioned accordingly. For the 16-on size of 1¼ × 1⅝ ins. (3 × 4 cm.) the camera carries two windows along the centre line of the back, each number being wound to the first and second window in turn.

Some cameras are equipped to take more than one size of picture on the same film. In particular, a number of cameras will take either 8 or 16 exposures on the standard roll of film. The back of such cameras carries an extra window that is only used when taking the half-size frame, and a half-size mask that is slipped into the negative aperture when the film is loaded. There are also cameras which will take all these formats; they have half-size and square masks and three safety windows. All cameras that give optional formats have some arrangement for masking the viewfinder or indicating the boundaries of the optional sizes.

Automatic Film Transport. More expensive modern roll film cameras (in particular the better-class single-lens and twin lens reflexes) have provision for advancing the film without reference to the numbering on the backing paper. The film transport itself may still be a knob or else a winding lever or crank. The transport movement automatically locks when it has advanced the film by exactly one frame interval.

There are several systems. In the simplest case the film is loaded in the normal way and wound on until the figure 1 on the backing paper appears in the safety window. From that point the window is covered and the amount of film used at any time indicated on a visible counter. The film counter (and the locking system) may be driven by a spring-loaded wheel bearing on the edge of the film inside the camera, or it may simply be coupled to the film transport shaft. In the latter case some compensating device usually allows for the growing diameter of the take-up spool as the film winds up on it, to ensure reasonably even spacing of the frames on the film.

Many current roll film cameras have no safety window at all. There the procedure during loading is to wind the backing paper until a reference mark on it comes opposite a locating mark in the camera back. The latter is then closed and the film wound until the transport locks. The distance from the reference mark to the first film frame is standardized, so that a given number of turns of the film transport shaft automatically brings the first exposure on the film into position by the time the transport locks.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Some cameras even have a film feeder system, where the backing paper passes between two spring-loaded rollers. When the beginning of the film, attached to the backing paper by adhesive tape, passes through the rollers, it initiates the film locking and counter mechanism.

Coupled Film Wind and Double Interlock. To prevent accidental double exposures on one frame of film, the film transport system of a camera may be coupled with the shutter release in such a way, that it is impossible to press the release until the film has been advanced after an exposure. Conversely, the transport lock is only freed by releasing the shutter. With such cameras there is often some way of putting the device out of action to permit intentional double exposures.

The film transport may also be coupled with the shutter to tension the latter automatically during the advance of the film.

Normally cameras with any form of double exposure lock only have a single B setting for time exposures on the shutter. Long time exposures must be made with a cable release and a locking arrangement. The T setting, available on shutters for cameras without double exposure lock, cannot be used in this case, since it requires a second pressure on the shutter release to close the shutter. The double exposure lock makes such a second pressure impossible until after the film has been advanced.

In addition to coupling the film and shutter setting operations, some cameras also have a device which operates when the setting knob has not been turned on after the last exposure. An internal metal shutter automatically masks the viewfinder after the shutter release is pressed, warning the user that he must wind on the film before he can take another photograph.

MINIATURE CAMERAS

As 35 mm. film has no backing paper, its frames cannot be visibly numbered as they are with roll film. On the other hand the film is perforated, and the transport system usually works through the perforations. It comprises a winding lever or knob, a transport sprocket, and a film (exposure) counter.

MINIATURE FILM TRANSPORT. The sprocket wheel, geared to the take-up spool, pulls the film out of the cassette. On modern cameras a rapid winding lever works the mechanism.

Transport Sprocket. This is a shaft carrying (usually) two sprocket wheels which engage the perforations of the film at the two edges. The sprocket thus pulls the film through the camera. It is directly linked with the transport movement and incorporates a lock which arrests the shaft when the right length of film has been pulled through. With the standard 24 × 26 mm. frame, eight film perforations correspond to one picture. With cameras taking 24 × 24 mm. pictures the transport lock is arranged to stop the movement after six perforations, and for 18 × 24 mm. frames after four perforations.

The usual location of the sprocket is between the film window in the camera back and the take-up spool. Some cameras have a single transport sprocket set in the film track. In either case the sprocket only rotates in one direction, but can be disengaged from the transport movement to turn freely in either direction for rewinding the film.

The Lever Wind. On most current 35 mm. cameras the film transport control is a lever operated by a flick of the thumb or finger. Frequently this folds into the camera when not in use.

Usually a single swing of the winding lever advances the film by the right amount for one exposure. On some cameras the film can also be advanced by a number of short swings, the lever locking after a transport movement corresponding to one film frame. On cameras which have this provision, the lever must be pulled up to its fullest extent to complete the transport movement. The lever then flies back under spring action to be ready for the next transport cycle.

Miniature cameras of older design have a transport knob instead of a lever. This requires turning, but is geared again to the sprocket and take-up spool.

A number of unorthodox film transport movements have also appeared from time to time: levers on the camera front, plungers in the top or at the side etc.

The winding movement is also linked to the take-up spool which winds up the film. This linkage is usually a friction drive so that the spool can slip on its shaft as it gradually gets full, to keep its movement in step with the transport sprocket. A few cameras have used a direct gearing between the transport lever or knob and the take-up spool, dispensing with the sprocket. In this case the spacing of the frames on a film is uneven, since the spool diameter increases as more film is wound on it.

The Film Counter. In a 35 mm. camera a mechanical counter keeps track of the number of frames exposed of a cassette load of film. This film counter or exposure counter is geared to either the transport sprocket or the shutter tensioning mechanism. It consists of a graduated disc which rotates by one division as the film is

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

FILM COUNTERS. 1. Film counter of miniature camera, reset to zero by a setting button. 2. Automatic film counter, resets itself to zero on opening the camera after unloading. 3. Counter in transport lever, manually set at any time. 4. Interchangeable film counters for certain multi-format twin-lens reflexes. 5. Film counter of twin-lens reflex coupled with transport crank.

advanced, or turns through about one revolution ending up with one division further—as read off opposite an index mark.

On most cameras the film counter is reset to its starting point after loading a film. The film itself is usually loaded in light-tight cassettes, with the beginning of the film protruding. After threading the film into the camera the exposed film leader has to be wound up on the take-up spool with the camera back closed, to ensure that a fresh and unfogged piece of film comes into position behind the film window for the first exposure. This involves making two or three "blind" exposures beforehand. Many film counters, when set to a starting index, automatically show when sufficient film has been advanced to take up the fogged beginning.

More advanced and expensive 35 mm. cameras may have an automatically resetting film counter. Here the counter returns to 0 on its own on opening the camera back or withdrawing the take-up spool (where this is removable).

There are two common counting systems: from 0 upwards (to about 40) to show the number of frames exposed; or from 36 backwards to No. 1, to show the number of frames still left on the film. In the latter case the counter must be started at a point corresponding to the actual length of film in the cassette. Beyond that the difference between the two systems is merely a matter of calibration and personal preference.

Double Exposure and Film Lock. On most current 35 mm. cameras the film transport is linked with the shutter tensioning mechanism, so that accidental double exposures become impossible. The film transport lock is in turn linked with the shutter release, to prevent blank frames (the advance of a film without taking a picture).

Deliberate double exposures are usually possible by disengaging the transport sprocket (by means of a reversing button or clutch) while working the transport lever. This tensions the shutter without advancing the film. Some camera designs incorporate a film release button to release the transport lock for deliberate film advance without exposures; this is useful when a partly exposed film has to be reloaded. The double exposure and film release functions may also be provided by various other means.

On cameras with interchangeable magazines the film transport mechanism may be interlinked with certain other safety locks to prevent inadvertent removal of the camera magazine without first closing the film apparature.

Rewinding. Since the film is wound on to the take-up spool from a light-tight cassette but does not itself have any backing paper or other protection, it must be rewound into the cassette when the whole film length is exposed. Otherwise opening the camera would fog and therefore ruin the whole film. The rewind mechanism on a 35 mm. camera consists of a knob which may have a built-in folding crank. This acts on a shaft which engages the centre spool of the cassette. To permit winding, the transport sprocket must first be disconnected to enable it to turn backwards. This is achieved with a reversing clutch in the form of a button, lever or similar device. The film is then rewound against the resistance of the friction drive of the take-up spool.

On a few cameras the film counter also moves backwards to its starting point during rewinding; usually however the film counter mechanism is disengaged as well. The point at which rewinding should be stopped can generally be felt by the resistance as the film leader is pulled off the take-up spool. Further rewinding pulls the film leader into the cassette. This is of no great importance if the complete film was exposed, but rewinding should stop before the film leader is withdrawn into the cassette if a partly exposed film has to be reloaded again.

A few cameras can work with a light-tight take-up cassette instead of the bare spool; in this case no rewinding is necessary and the full

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

take-up cassette can be unloaded from the camera at the end of the film. Certain rapid loading systems, employing a completely enclosed film magazine with light-tight feed and take-up compartments also need no rewinding.

Rapid Winding Systems. Quick-operating devices are available for some 35 mm. cameras to transport the film even faster than is possible with the normal lever wind. These accessories are useful for action photography and wherever a large number of exposures must be made rapidly.

For even higher operating speeds the film can be automatically advanced after each exposure by a spring motor attachment. With this device it is possible to make exposures at the rate of 2 or 3 per second. One or two makes of camera have such a spring—or electric—motor built in, and after the first pressure on the shutter release button, exposures are made automatically much faster than they could be made by hand. This type of camera will make a series of still photographs of an action lasting only a second or two.

In a fully motorized camera the motor automatically transports the film and retensions the shutter, leaving everything ready for the next exposure. When fully wound, a spring motor may be able to operate the complete exposure sequence a dozen or two dozen times. Electric motor film transport systems or attachments are usually also suitable for remote control. In this case the camera can be set up—for example for nature photography—and operated some distance away by the photographer who only has to press a button at the end of a remote control cable. This releases the shutter and actuates the transport and tensioning cycle. Remote control systems of this kind can even operate by wireless signals.

ULTRA-MINIATURES

Still cameras taking 16 mm. or even narrower film are generally loaded with single or double cassettes. With the single cassette the transport system is in the main a scaled-down version of a 35 mm. film transport. A sprocket here acts on the perforations of the film in the usual way. If the camera uses unperforated film, the transport mechanism acts through the take-up spool core. Ultra miniatures using a single cassette need rewinding of the film as with a 35 mm. camera.

In a number of cases, especially with two-cassette systems, the take-up cassette contains no spool. The film is then simply pushed into the take-up chamber where it curls up, guided by an internal spring. This design makes the cassette more compact, and is also found on a few 35 mm. cameras.

Ultra-miniatures may have a transport lever or knob, but a number of other systems are also popular. One of these is a push-pull action: the camera is pulled out of a housing which normally protects the lens and finder opening. This action of pulling out (or of pushing the camera into its housing) at the same time advances the film and tensions the shutter. The push-pull movement may also be linked with the opening of the viewfinder.

A number of sub-miniatures have a built-in spring motor or other rapid winding mechanism. This again permits exposure sequences at the rate of 2 or 3 pictures per second.

PLATE AND SHEET FILM CAMERAS

Plate Changing. There is at present no satisfactory way of changing plates quickly. Many ideas for loading plates in magazines have been tried in the past, but none of them survived the introduction of the roll film. Plates are never used when a number of exposures must be made in rapid succession, although press photographers, by long practice, can generally change a plate in about the same time as it takes to wind a film on by hand.

When a plate has been exposed in the camera, it is first made safe to light by replacing the dark slide and then the plate holder is removed by sliding it out of the guides that hold it in place at the back of the camera. A fresh plate holder is then slid into the guides and the dark slide is withdrawn. No inventor has yet succeeded in improving materially upon this sequence of operations. Some cameras have plate backs in which the plate holder is simply clipped in place; these are an improvement over those that slide into guides. Some have sections of the guides cut away so that the plate holder has only to slide about one quarter of the length of the guide.

All types of plate changing magazine are handicapped by the weight of the plates. Even if such magazines could be made to work satisfactorily, no one would willingly carry around up to a dozen plates in his camera when a single roll of film would serve the same purpose.

Sheet Film. Single sheets of film, which are in many cases replacing plates, are used in much the same way as the latter. They are loaded in sheet film holders with a dark slide, and the loading and changing procedure is as slow as it is with plates. A loaded sheet film holder is however lighter. Magazine operations with sheet film involves the use of a special packing, the film pack.

Film Packs. The film pack usually holds twelve exposures in the form of pieces of film cut to the plate size of the camera. Each piece of film is attached to a strip of black paper which forms both a backing paper and a leader by which the film is pulled into place before exposure. The films are packed card-fashion in a shallow metal box, and the paper leaders are folded back around the bottom edge of a separator so that when one of the leaders is pulled, the film is drawn down one side of the separator and up in front of the other.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CROSS-SECTION OF FILM PACK. A pile of 12 sheet films (3 shown here), each attached by one edge to a long strip of black paper, is placed inside a flat metal box behind a film aperture. The paper leaders go round behind the pressure plate, with the ends projecting as tabs outside the edge of the box. After exposure, the top film is moved out of the way round the back by pulling the paper tab, leaving the next film in taking position.

Film Pack Adapter (F.P.A.). A metal container, called a film pack adapter, holds the film pack and is attached to the back of the camera like a plate holder. To make an exposure the dark slide is withdrawn from the film pack adapter and the first paper leader is pulled up and torn off.

This draws away the outer sheet of black paper and uncovers the first film. When this has been exposed the second paper leader is pulled out.

This pulls the exposed film around to the back of the pack and uncovers the second film. The backing paper behind each film prevents light from passing through it during exposure and affecting the next film.

The film pack can be changed quicker than a roll film, and it has the added advantage that once the dark slide is replaced, the half-used pack can be removed from the camera, leaving it free to be used with either a focusing screen or another type of sensitive material. On the debit side; the film pack is the dearest way of buying sensitive material; it adds to the bulk of the camera, and the dark slide is another item to think—or forget—about.

SPECIAL TRANSPORT SYSTEMS

Large-Capacity Cameras. Certain types of industrial and commercial cameras have to carry large film loads of several hundred exposures to cope with a high work rate, without the loss of time involved in frequent cassette or roll changing. In principle these transport systems work on the same lines as the automatic transport of a 35 mm. camera: the film is wound on by a fixed distance after an exposure while the shutter is retensioned. Usually the transport system is driven by an electric motor which may be remote-controlled. Examples are cameras used in aerial photography, instrument recording, microfilm copying, etc.

Continuous Transport. For some types of photography the film in the camera is advanced not intermittently, frame by frame, but continuously. This is the case in all systems where the subject also moves past the camera at the same time. This permits exposures at a high rate and is used in such fields as aerial photography and mapping, microfilming, etc.

The main requirements of the transport system are a smooth movement of the film at a constant speed, and accurate matching of the film movement with the speed at which the object or objects flow past the camera. No shutter tensioning of film counting is involved, and the exposure takes place through a narrow slit immediately in front of the film.

Instant Pictures. In a few special camera systems processing takes place inside the camera and yields finished prints. In this case the film is advanced by pulling a protruding leader out of the camera after every exposure. The material is arrested at appropriate intervals by a mechanical device inside the camera.

FILTER BAG. Suitably dyed transparent plastic bag used to modify the colour of light sources, especially flash bulbs. The normal range of dye colours includes pale yellow and pale blue to lower or raise the colour temperature of flash bulbs for work with artificial light or daylight type colour films respectively. Special deep red or almost opaque filter bags have also been used for infra-red photography; with such a bag the flash bulb or lamp emits practically no visible light at all and can be used for infra-red photography at night without attracting attention. In use, the filter bag is simply fitted over the bulb before the exposure.

FILTERING. Filtering removes undissolved particles and other solid impurities from a solution. These may be present in freshly made solutions, and also accumulate as a sediment in developers, etc., during use. If not filtered out, they may settle on the emulsion during processing and either cause clear spots by preventing the developer from reaching the surface, or black spots if the particle consists of undissolved active chemical.

FILTER FUNNEL. Either cotton wool or filter paper will hold back solid particles. The paper is folded to form a cone which fits into the funnel and is supported by the sides.

CC-0. Arunachalam Digital Preservation Foundation, Chandigarh

A solution is filtered by being poured through a funnel lined with a porous material—e.g., a wad of cotton wool, or a cone made from a circular disc of the special filter paper that can be bought for the purpose. The finer the pores, the more efficient the filtering action—i.e., the smaller the particles of solid matter that will be removed.

But for the same surface area of the filtering material, the solution takes longer to pass through a fine material than one with more open pores.

Whenever possible, solutions should be filtered while hot, as the process is then quicker. Solutions run through cotton wool more rapidly than through filter paper, but paper is more efficient.

It is as well to use a large funnel for filtering solutions because it can be filled up and left without attention whereas a small funnel must be constantly topped up. If the solution is being filtered into a bottle, the stem of the funnel can be inserted in the neck of the bottle and no support is needed. But if the solution is being filtered into a dish, the funnel should be mounted on a filter stand. This consists of a metal ring or a clamp to hold the funnel, clamped to the vertical pillar of an ordinary chemistry laboratory retort stand.

FILTERS

Filters are used in photography to modify the light falling on the subject or passing through the camera lens. Thus we have camera filters which are coloured discs of glass or gelatin placed on the lens, and lamp filters which are placed in front of the light source.

As their name implies, filters actually stop some of the light falling on them, so that the colour or nature of the light which passes through is changed. With coloured filters, the light which they pass is governed by the actual colour of the filter: thus a yellow filter will pass red and green light, but tend to stop blue light. In this way, by controlling the proportions of colour coming from the subject (or light source), the relative tones in the negative and final photograph can be modified.

There are five main reasons for wanting to use a filter:

(1) To correct the imperfect colour sensitivity of the film, and make it translate the subject into tones of grey of more or less the same brightness as the colours appear to the eye. Such filters are called correction filters.

(2) To distort (brighten or darken) the reproduction of certain colours for special effects. This intentional distortion is used in pictorial photography and in certain commercial and scientific work. Filters used in this way are called effect filters or contrast filters.

(3) To change the colour temperature of the light. This is important for colour photography. Such filters are called colour compensating filters.

(4) To take pictures by the light of a single colour only; mainly for scientific and other special purposes such as telephotography by infra-red light. In principle, most of these filters are extreme cases of the contrast filters mentioned above.

(5) To take photographs by polarized light, or to cut out the effect of polarized light in photographs. Such filters are called polarizing filters.

Gelatin Filters. The commonest camera filters are thin pieces of dyed gelatin. They are easiest to make accurately, and offer the widest range of colours.

Gelatin filters are cut to the required size and used in front of the lens in special holders. For better protection the gelatin discs may even be mounted between the lens elements themselves.

As gelatin filters are very sensitive to mechanical injury, they should be carefully protected against scratches, dirt, dust, grease and moisture. The gelatin surface must never be touched with the fingers as it is almost impossible to clean.

ACTION OF A FILTER. Filters act by holding back some of the light reaching them. They pass almost all the light of their own colour, but appreciably reduce the intensity of light rays of different colours. As a result they also call for extra exposure.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

FILTER ABSORPTION. A filter usually has its maximum transmission in one particular region of the spectrum. It will lighten objects of its own colour, and darken others to an increasing degree the farther away they are on the spectrum scale. Thus a red filter will darken blues most, as blue is at the other end of the spectrum. A green filter will darken both blue and red.

Gelatin Glass Sandwich. Where gelatin filters have to be constantly handled, they are usually cemented between glass. The workmanship of the cementing and the quality of the glass are important. If the glass surfaces of the filter are not absolutely flat and parallel the thickness of the glass may upset the optical properties of the lens. The danger is less with unmounted gelatin filters which are so thin that they have practically no effect.

The best filters for high quality scientific work are prepared as optical flats of guaranteed accuracy. For most normal photography where such high precision is not needed, the gelatin is usually cemented between flat and polished plate glass.

Cemented filters must be treated with the same care as camera lenses. They should never be allowed to get wet or dirty. Although the edges of the filter sandwich are usually sealed, moisture and cleaning fluids will in time penetrate and affect the cement or the gelatin. Filter holders which exert uneven pressure on cemented filters upset their optical parallelism, particularly of those of the highest quality.

Some modern cemented filters have dyed cellulose sheets instead of gelatin.

Glass Filters. Much more robust filters are made from mass coloured glass. Such filters consist of glass only. While they are not so easily damaged, the range of colours in which they can be manufactured is more limited. The optical accuracy of the best solid glass filters can be as high as that of an optical flat.

Lamp Filters. Filters are also made in the form of lamp filters which are large thick sheets of dyed gelatin. They are placed over the lamp or other light source, and not over the camera lens. As they cannot affect the performance of the lens, their optical quality does not matter and they do not call for any special care in handling.

Where the subject is illuminated by a number of lamps, it is generally more economical and easier to make any colour correction by using a filter in front of the camera lens. But lamp filters are useful for dealing with only part of the lighting—e.g., for special effects in colour photography. Sometimes a lamp filter is used to limit the colour of the lighting to one particular wavelength as in photography by infra-red and ultra-violet light.

Liquid Filters. For scientific work special filter effects may be required which are not obtainable or practical with normal ready-made gelatin or glass filters. There it is often most convenient to use solutions of certain coloured chemicals in suitable glass cells. The thickness of the cell (i.e., the thickness of solution placed in the path of the light) determines the degree of absorption, while the choice of substance gives the necessary absorption characteristics. Liquid filters may be also used for absorbing heat.

Chemicals used for liquid colour filters are largely inorganic salts, for instance potassium bichromate (orange), ammoniacal copper sulphate (blue-violet), copper sulphate or nitrate (blue-green), iodine in carbon tetrachloride (violet) or in potassium iodide solution (brown), various nickel and cobalt salts, etc. Visually colourless solutions (e.g., sodium nitrite) are also used as ultra-violet filters. Suitable combinations of several solutions—usually in separate cells—can isolate very narrow bands of the spectrum.

The main advantage of liquid filters—apart from their versatility and cheapness—is the exact reproducibility of characteristics. These depend on variables which are easily controlled with great precision; namely cell thickness, and composition and strength of the solutions used.

Absorption Curves. Filter characteristics are specified by absorption curves which plot the filter density against the wavelength of the light. Such a curve therefore shows the wavelength of maximum transmission (i.e., the predominant colour of the filter) as well as the amount of light of other colours passed through. The individual points of the curve indicate relative—i.e., percentage—absorption and transmission of each wavelength. The shape of the curve corresponds to the absorption with a light source of equal energy throughout the

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

TYPICAL ABSORPTION CURVES OF CORRECTION FILTERS. 1. Colourless ultra-violet filter for high altitudes and colour film. 2. Pale yellow filter for slight correction. 3. Medium yellow filter for normal correction. 4. Deep yellow filter for over-correction. 5. Very deep yellow (minus blue) filter, often used in photomicrography. 6. Yellow-green filter.

spectral range covered, though the curve is rarely obtained by direct measurement with such a source.

Absorption curves are significant with separation filters for three-colour photography, where they help in correctly matching a set of filters for the most suitable overlap in absorption ranges. In other fields, too, the curve is a help in selecting the best filter for a particular purpose.

Filter Factors. Filters affect the colour of light they pass by holding back some of it. So they call for a longer camera exposure to compensate for the light lost. In practice the exposure time is multiplied by a filter factor.

Usually filter factors—other than the lowest values—are rounded off to the nearest whole number. This is accurate enough for everything except certain sensitometric work. In ordinary photography the difference between factors of 3·8 and 4 or 4·2 is too small to matter. In fact, errors up to 20 per cent can be ignored.

Instead of increasing the exposure time, we can widen the lens aperture. Here again, setting the aperture to the nearest half stop is quite accurate enough for ordinary photography.

The filter factor is not a constant number. It depends on: the colour and depth of the filter; the colour sensitivity of the film or plate; the colour of the light; the colour of the subject.

So to know the factor of a particular filter, we must also know the colour sensitivity of the film and the colour of the light. For really accurate tone reproduction we may have to know the colour of the subject as well.

The filter colours may vary from that of pale yellow or green correction filters to that of deep effect and monochromatic ones. Generally, the deeper the colour of the filter, the more light it holds back, and the higher its factor.

Filter manufacturers always provide a set of tables giving filter factors for the various conditions normally anticipated.

Filter Factors and Exposure Values. For cameras which carry an exposure value scale, filter factors can also be expressed in terms of the required exposure value correction. Many modern filters in fact carry both the orthodox factor and the exposure value correction.

The exposure value correction is always a negative number (the use of filters increases the exposure required and hence reduces the exposure value setting). Exposure value corrections are usually given in half or whole numbers: $-\frac{1}{2}$ E.V. corresponds to a filter factor of $1\frac{1}{2}\times$, $-1 = 2\times$, $-1\frac{1}{2} = 3\times$, $-2 = 4\times$, $-2\frac{1}{2} = 5$ to $6\times$, $-3 = 8\times$, and so on. The exposure value correction also corresponds to the number of lens stops by which the lens must be opened up when using the filter.

Negative Material. The colour sensitivity of the film plays its part because some films are excessively sensitive to certain colours and thus need lower filter factors for filters of those colours. We can classify films and plates according to their colour sensitivity as follows:

Blue sensitive materials are sensitive to ultra-violet, violet, and blue light only. They are rarely used with filters, and then only with pale yellow ones, which have a high factor when used with this type of material.

Slow orthochromatic materials are sensitive to ultra-violet, violet, blue, blue-green, and slightly to green.

Fast orthochromatic materials are sensitive to yellow-green and yellow as well, but to a much greater extent to violet and blue. With both slow and fast orthochromatic materials yellow and yellow-green filters (to reduce the excessive blue sensitivity) are the only ones that can be used.

Red panchromatic materials are sensitive to all colours of the spectrum, and excessively sensitive to orange and red. They thus need comparatively low filter factors with red filters.

Correct panchromatic materials are also sensitive to all colours, but their sensitivity is more balanced. Thus they are not excessively red sensitive, and need higher filter factors with red filters.

Infra-red materials are highly sensitive to violet and blue, almost insensitive to blue-green, green, yellow, and orange, and sensitive to red and infra-red. They are used with special deep red or infra-red filters only.

Colour of the Light. The colour of light depends on the light source. Daylight is more blue (has a higher colour temperature) than tungsten electric light. Thus in daylight blue filters need lower filter factors, and red filters higher.

With artificial light, which is comparatively redder, red filters need lower factors

APERTURE CHANGES WITH FILTER FACTORS

For a factor ...	$1\frac{1}{2}$	2	3	4	5–6	7–9	10–13	14–18	20–27	30–35	
Increase aperture by	$\frac{1}{2}$	1	$1\frac{1}{2}$	2	$2\frac{1}{2}$	3	$3\frac{1}{2}$	4	$4\frac{1}{2}$	5	stops

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

and blue filters higher factors than by daylight.

For really accurate scientific or reproductive work and also for colour photography, the smaller variations in colour between different types of artificial light must also be allowed for—e.g. low power household lamps, high power studio lamps, Photofloods, etc. Even the colour temperature of daylight depends on the time of day and on the weather. But for all normal work these variations can be ignored.

SUMMARY OF CORRECTION FILTERS

Filter	Daylight Factor LO	Daylight Factor O	Daylight Factor P	Daylight Factor R	Art. Light Factor O	Art. Light Factor P	Art. Light Factor R	Effect
Ultra-violet	1½	1¼	1¼	1¼	*	*	*	Used to darken sky at high altitudes
Pale-yellow	2	1½	1½	1½	1½	1½	1½	Slightly darkens sky tones
Medium-yellow	3	2	1½	1½	2	1½	1½	Darkens sky; bring out clouds
Deep yellow	5	3	2½	2	2½	2½	2	Very full correction of sky tone
Yellow-green	4	2½	2	2	2½	1½	1½	Slightly darkens sky, also darkens red with pan film
Pale green	*	3	3	3	3	2½	2½	Correct tones on pan film for outdoor portraits, etc.
Medium green	*	*	3½	4	*	3	3½	Fully correct tone reproduction on red pan
Pale blue		*	*	*	*	1½	1½	Correct tones on pan films in artificial light

LO = slow orthochromatic, O = fast orthochromatic, P = correct panchromatic, R = red panchromatic.
* There is no point in using this film-filter combination under these circumstances.

Special light sources such as arc lamps, gas or mercury vapour discharge tubes, etc., have their own filter factors. They are usually published by the manufacturer of the film or plate likely to be used under such conditions.

Correction Filters. Nearly all orthochromatic and panchromatic materials are excessively sensitive to blue. This means that in subjects like landscapes, the blue sky is much too light in the final print. The tone difference between the sky and white clouds is also lost.

Both these troubles can be overcome by using a yellow filter. This colour works equally well with orthochromatic and panchromatic materials. The depth of the filter used depends on the amount of correction required.

Some correction of orange and red tones, in addition to blue, may also be desired with panchromatic materials, especially those of increased red sensitivity. Thus, outdoor portraits of sun-tanned faces will look too pale without a filter to reduce the excessive red sensitivity. Moreover, for recording and similar work, completely correct tone reproduction is often wanted. Here a yellow-green or green correction filter should be used with panchromatic materials.

As long as these filters are not too deep, they can be used with orthochromatic as well as panchromatic materials. With orthochromatic materials they are no better than yellow filters, because there is no red sensitivity to correct. But they are useful when we wish to carry as few filters as possible and have to work with both ortho and pan materials. A yellow-green or pale green correction filter is the best all-round filter for such occasions.

The excessive red sensitivity of some panchromatic films and plates also makes itself felt in photography by tungsten filament electric lamps. In portraits especially, flesh tones are reproduced too pale, red lips hardly show at all unless heavily made up with lipstick, and blue eyes become too dark. A pale blue or blue-green correction filter is therefore used.

Orthochromatic films are always highly sensitive to blue light and therefore never need a blue filter.

At very high altitudes the blue sky tends to reproduce as a fairly deep tone on panchromatic film and in mountain and Alpine photography a pale yellow filter gives all the correction necessary. At altitudes above 5,000 feet a special colourless U.V. (ultra-violet) filter is often used.

Sky Filters. Yellow and yellow-green correction filters are often loosely called sky filters because they are commonly used to darken the sky tones. But this name is more especially applied to the graduated correction filters. These are filter discs of which the top half is coloured, and gradually fades away towards a colourless lower half. They are used in landscape photography when only the sky is to be toned down, while the foreground requires no correction.

The light from the sky passes through the top (coloured) half of the filter, and the light from the subject through the bottom (colourless) half. As the camera exposure is given to suit the foreground, these graduated filters do not need increased exposures, and have a factor of 1.

GRADUATED SKY FILTER. Top: *This should be mounted a little way in front of the lens to be effective so that rays from the sky are filtered, but rays from the foreground are not.* Bottom: *Mounted close to the lens it is unable to separate the rays from sky and foreground, and filters both equally.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PRACTICAL FILTER EFFECTS. The subject is a red house standing in a green field, with a yellow roof, and a blue sky above it. Left: *A shot taken through a red filter will show the sky virtually black, the house and roof almost white, and the green grass very dark.* Centre left: *A yellow filter darkens the sky, lightens the red walls, reproduces the roof almost white, and records the grass in approximately its correct tone.* Centre right: *A green filter darkens the sky as well as the red house, lightens the greens, and leaves the yellow more or less unchanged.* Right: *A blue filter reproduces the sky almost white, and darkens the other colours especially red. It would hardly be used in practice (except for making colour separation negatives).*

To be effective, the sky filter is not fixed directly on the lens, but a little distance in front of it, in a special holder. Some of these filters are square and fit in holders which allow the glass to slide up and down in front of the lens. The centre of the filter can thus be adjusted to the height of the sky line in the picture. This adjustment can only be made accurately on a camera with a focusing screen.

Effect and Contrast Filters. Orange and red effect filters are used to carry the modification of sky tones beyond correct reproduction, to give specially dark dramatic skies.

In addition, filters of the various colours are made to emphasize the brightness of certain colours in the subject (e.g. flowers), and to bring out or play down certain tones in copying and other fields such as photomicrography for which special sets of contrast filters are made.

Here the task of the effect and contrast filters is mainly to increase the tone contrast between the colours which would otherwise photograph as similar tones of grey. If, for instance, red and green are reproduced in their correct brightness on normal panchromatic film, they both look about the same. To differentiate between them, we can use either a red filter which will lighten the red and darken the green, or a green filter which will darken the red and lighten the green. Deep yellow will, of course, also act as a contrast filter.

Contrast filters are almost exclusively used with panchromatic materials.

We can best visualize the effect of these filters by laying out the main spectrum colours in their natural order: blue—blue-green—green—yellow—orange—red.

Any filter will darken the tones of colours farthest away from its own colour on the spectrum scale. At the same time, the filter will lighten the tone of objects of its own colour, and it will make objects of neighbouring

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

colours come out slightly lighter. Thus blue will be reproduced much darker with a red filter than with a yellow; green will come out as a much lighter tone with a green filter.

SUMMARY OF CONTRAST AND EFFECT FILTERS

Filter	Daylight Factor P	Daylight Factor R	Art. Light Factor P	Art. Light Factor R	Effect
Blue ...	5	7	10	15	Darkens red, yellow lightens blue
Green ...	6	7	6	7	Darkens red, orange, slightly darkens blue, lightens green
Deep yellow	2½	2	2½	2	Darkens blue, lightens yellow, orange
Orange ...	5	4	2½	2½	Darkens blue, green, lightens orange, red
Light red ...	7	4	4	3	Darkens blue, green, lightens orange red. Generally increases image contrast
Deep red ...	16	8	8	6	As light red, but with greater effect

P = correct panchromatic, R = red panchromatic.

Colour Separation Filters. Separation negatives for making colour prints are taken in sets of three through the tricolour filters, red, green, and blue.

Normal tricolour filter sets are used to make colour separation negatives directly from the subject. The filters are more or less the same as the contrast filters of the same colour.

Special narrow-cut tricolour filter sets are used to make indirect colour separation negatives from colour transparencies. These filters pass light of practically only their own colour.

With either type of tricolour filter the filter factors must be highly accurate, as even small errors upset the colour balance of the final colour print. The exact colour temperature of the light source is also much more important. These factors are generally supplied by manufacturers for specific films or plates, since general factors as used with correction and contrast filters are not accurate enough.

Filters for Colour Film. In colour photography the main function of the filter is to correct the colour rendering of the picture by matching the colour balance of the film to the colour quality of the lighting, or by compensating for inherent deficiencies of certain light sources. In colour print making filters are also used to control the colour rendering and balance of the finished print.

Filters for colour work are mostly very much paler than for black-and-white films, and they are confined to rather fewer colours. The normal correction and effect filters for black-and-white film cannot be used with colour film; they would yield a colour picture with a very strong predominant colour tint of the filter itself. (But strong filters are used sometimes for special pictorial colour effects.)

The four main groups of filters used in colour photography: light balancing filters, conversion filters, colour compensating (C.C), filters and general correction filters.

Light balancing filters modify the colour temperature of the light passing through the filter. They are available usually in two series: bluish (to raise the colour temperature) and reddish or amber (to lower the colour temperature). Such filters are sometimes calibrated in the actual decamired shift reproducing the colour temperature: for instance an R3 filter makes the light passing through redder by 3 decamireds.

Conversion filters are a special kind of light balancing filter to adapt specific types of colour film to a different colour temperature. Usually they are recommended by the makers of a given colour film for matching that film with a given light source. The effect of such conversion filters may vary slightly with colour films of different makes though of the same nominal colour balance. The commonest filter of this kind is the type A filter used for adapting artificial light (photo-flood) type colour film to shooting in daylight.

Colour compensating filters have specific absorptions in one or two colours to compensate for colour deficiencies or irregular balance of special light sources (such as fluorescent tubes, electronic flash, etc.). These filters are also used for controlling the light when making colour prints or transparencies by the negative/positive or reversal systems.

The commonest C.C. filters are cyan, magenta and yellow series in various densities from 0·05 to about 0·9. These densities are equivalent densities to light of the complementary colour. The filter designation in most cases indicates both the colour and the equivalent density by a code: thus a CC20M filter is a magenta filter with a density (to green light) of 0·20. C.C. filters also exist in red, green and blue. These are equivalent to combinations of the corresponding complementary colours.

General correction filters for colour include haze and skylight filters, which mainly absorb ultraviolet and a certain amount of blue light. They correct for the excessive blueness for colour pictures taken of distant subjects in the presence of atmospheric haze, and shots in cloudy weather.

Filter Factors for Colour. Filters for colour photography rarely have high factors, since the correction required is usually fairly small. Light balancing and conversion filters of the reddish or amber series usually have factors between 1¼ and 2 ×; bluish filters have generally higher factors (up to 3 or 4 ×). The factors for haze and skylight filters usually vary between 1 and 1½ ×.

Haze Filters. Detail in distant landscape views is generally obscured by atmospheric haze. Haze is simply light scattered by the water vapour and dust particles in the atmosphere, and it is mostly composed of blue and ultraviolet light—hence its blue colour.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Most photographic materials are unduly sensitive to light of this colour and they tend to over-emphasize the effect of the haze in the finished photograph. So they lose even detail that the eye could distinguish when the photograph was taken. But the haze can be greatly reduced by using a yellow filter which holds back the scattered blue and ultra-violet light.

This penetration of the haze increases as the filter cuts out more and more of the blue end of the spectrum, therefore it is more marked still with orange and red filters.

This bluish haze is also objectionable in colour photographs of distant scenery. Here, a colourless, ultra-violet-absorbing, or a very pale yellow filter may be used. But anything more pronounced than the palest yellow completely falsifies the colour balance.

Infra-red Filters. An extreme degree of haze penetration is possible with infra-red film used with an infra-red filter. This combination cuts out all visible rays and passes only infra-red light which is not scattered at all by the atmosphere. We can thus get extremely clear pictures of long distance shots. This technique is therefore greatly used in aerial photography and survey.

The infra-red filter makes skies come out jet black. Green leaves, plants, etc., reproduce almost white because the chlorophyll (green colouring matter) in the plants strongly reflects infra-red light. The result resembles snow photographs by moonlight.

Infra-red filters (with infra-red film) find much use in medical photography and research; e.g. for photographs to show the structure of the blood vessels below the skin surface.

Various other materials, including semi-charred carbon, reflect infra-red light. Thus charred documents can be deciphered if they are photographed by infra-red light, because the charred paper still reproduces as a light tone.

Invisible Light Filters. Infra-red lamp filters can be used over a light source such as a flash bulb for night photography by invisible light. The infra-red filter cuts off all visible illumination, passing only the invisible infra-red which lights up the subject and records the image on the film.

Invisible light photography is also possible with ultra-violet light. Many substances glow in the dark when exposed to invisible ultra-violet rays. This fluorescence is used to distinguish between different inks and pigments which look identical in ordinary light. Ultra-violet light photography is thus a valuable tool in examining paintings and documents for suspected forgeries.

Here again the ultra-violet filter is placed over a special ultra-violet lamp, cutting out all visible light. (This filter must not be confused with the colourless ultra-violet filter used over the camera lens for mountain and high altitude photography. The colourless filter absorbs ultra-violet light, while the lamp filter absorbs everything except ultra-violet light.) When photographing by ultra-violet light, a colourless filter is usually placed over the camera lens, since in most cases we want to record not the ultra-violet light itself, but only the fluorescence.

Spectrum Filters. These are contrast filters used in scientific work. They transmit only a narrow band of wavelengths—in effect only one colour of the spectrum.

For even greater accuracy, the scientist uses interference filters. These are colour filters which derive their colouring not from any dye or pigment, but purely from optical interference. The colours are therefore very pure (i.e., the transmission bands much narrower than with conventional dyed filters), and are not liable to fade or deteriorate.

Polarizing Filters. These can cut out light which has undergone an orientational change known as polarization.

Light is polarized when it is reflected from the surface of any transparent medium. This includes glass, water, the glaze on china and pottery, varnishes, polishes, etc. The amount of polarization depends on the exact angle at which the light is reflected from the surface. Metallic surfaces do not polarize light on reflection.

The light from the blue sky, particularly at right angles to the position of the sun, is also polarized.

The two main uses of polarizing filters therefore are to reduce or eliminate surface reflections when photographing subjects behind glass, under water, etc., and to darken blue skies without affecting the rest of the scene. This property is particularly useful in colour photography, where any other type of filter would upset the colour balance of the film.

The polarizing filters sold for photography are usually sheets of a polarizing substance prepared in plastic form, and mounted between

UNEVEN ILLUMINATION. A central light beam A traverses a shorter path (a) through the filter than an oblique beam B with its path (b). The filter thus tends to darken image portions near the edge of the field more than in the centre.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

glass in much the same way as gelatin filters. The position of a polarizing filter on the lens is important; it is effective only if its polar axis is at right angles to that of the light it is intended to hold back. In practice, the subject is looked at through the polarizing filter and the filter is rotated until the objectionable reflections are reduced to a minimum. There is usually a handle, or some kind of reference marks on the mount so that the filter can be fitted to the lens in the position that gives the best visual result.

Optical Limitations of Filters. Lenses are usually corrected for use on their own; the addition of any other optical element, even a filter, is liable to impair the maximum performance of the lens. Imperfections of the filter (lack of parallelism of the filter surfaces, flaws, also dust and dirt) can cause loss of sharpness and loss of contrast. For high quality work filters must therefore be as precisely made as the lens itself.

The thickness of the filter, especially with a lens having a wide image angle (where an appreciable portion of the light rays go through the filter obliquely) enhances the falling off of illumination towards the edges of the field. Oblique rays have a longer path to travel through the filter, and thus more of the light is absorbed. At close range the difference in the light path through the filter glass at the centre and at the edges of the field may also upset the optical correction of the lens, and cause a slight degree of distortion. This is greater with glass filters than with the thinner gelatin filters; for highly accurate work the latter are therefore preferable.

Generally it is best to avoid using a filter where it is not really necessary. In particular the practice of keeping an ultra-violet filter permanently on the lens for protection is not in the interest of maximum lens performance. L.A.M.

FINALITY DEVELOPMENT. Procedure of developing an image until all the silver salts affected by light have been reduced to silver.

In normal negative development the action of the developer is stopped at a specified stage, depending somewhat arbitrarily on the contrast and density required. The time taken to reach this stage depends on the developer, but is a matter of minutes and has to be carefully controlled in each case to yield consistent results.

In finality development the action of the developer is carried on as far as it will go, until the image reaches gamma infinity. In practice that involves developing the negative material for up to hours in the normal developer.

Finality development has the following results:

(1) The effective emulsion speed increases because all the exposed silver salt is reduced instead of only part of it. The actual gain in speed in terms of shadow detail reproduced is in the region of 60–120 per cent, although exaggerated claims have put it as high as 800 per cent.

(2) The image contrast greatly increases. As a result, the density in the medium tones and highlights becomes very great, and the slightest over-exposure yields an almost unprintable negative.

(3) The fog level increases.

(4) The grain increases; this procedure is not, therefore very suitable for miniature work.

(5) The exact development time is not critical.

In practice, the disadvantages under 2, 3 and 4 greatly outweigh the advantage of extra speed. Finality development was, however, specified as standard procedure in the old (1931) DIN standard of film speed ratings. This was one of the reasons why that particular DIN standard was never accepted for international use.

Finality development is nevertheless popular for papers, where the increase in contrast and density is not so great, and the image grain does not matter. In this case finality development has the added advantage of yielding superior image tones (except with some chlorobromide papers). Development must, however, still be stopped before the appearance of fog although fogging is generally delayed by suitable restrainers or developer improvers.

At normal temperatures, chloride papers are developed to finality after about 1–1½ minutes, chlorobromide and bromide papers after about 3–4 minutes. L.A.M.

FINDER. Abbreviated name for viewfinder. A sighting device built in or attached to a camera through which can be seen an area of the subject corresponding more or less exactly to the image focused on the sensitized material during exposure.

See also: *Viewfinders.*

FINE GRAIN TECHNIQUE. Whenever negatives are printed by enlargement, the fineness of the grain in the image is important. This applies especially to miniature work where the negative sizes of around 1 × 1½ ins. often require considerable magnification. Coarse grain shows itself in an uneven, broken-up

appearance of the image tones—particularly in the medium densities—which is generally more pleasant. One of the aims of miniature technique is therefore the production of fine grained images.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

The factors affecting the fineness of the grain in the finished picture are:

(1) Choice of negative material.
(2) Exposure of the negative.
(3) Choice of negative developer.
(4) Degree of negative development.
(5) Choice of enlarging illumination.
(6) Choice of paper.
(7) Degree of enlargement.

In brief, the best results are obtained by using a fine grain film, correct exposure, normal fine grain development to a moderate gamma, and enlargement in an enlarger with semi-diffused or diffused lighting on a normal paper grade.

Negative Materials. The most important factor determining the graininess of the final image is the size of the silver halide grains in the negative emulsion. Special fine grain materials are available for miniature photography. They tend to be comparatively slow, but should be chosen whenever the extra speed of hypersensitive materials is not essential.

Provided the intrinsic grain of the emulsion is sufficiently fine, the other points of fine grain technique are considerably less important. They can, however, help to keep down the graininess with what would otherwise be a comparatively coarse grained film.

Negative Exposure. Over-exposure tends to increase the grain of the negative image, even though the latitude of the emulsion may be able to cope with excessive exposures. To make the most of the limited fineness of grain with faster emulsions, the exposure should be the minimum required to yield adequate shadow detail, but no more. The use of some exposure guide—preferably a meter—for really accurate exposures is therefore desirable. Current ASA speed ratings are designed to yield minimum correct exposures; for most consistent results calibration of the exposure meter to the film is advisable.

Fine-Grain Developers. Energetic developers tend to clump the silver grains in the image into larger aggregates. Fine grain developers generally are formulae of curtailed activity, using either a low concentration of alkali (or else weak alkalis) to keep the pH down, and/or low-energy developing agents, and/or silver solvents.

Many of these developers also lower the effective emulsion speed, especially with fast films. Generally it is better to use a moderate fine grain developer with a fine grain film than an ultra-fine grain developer with a fast coarse grained film. The effective speed of the latter combination may be no higher than of the former, and the contrast is likely to be lower for the same degree of graininess. High-speed negative materials are intended for occasions where subject conditions demand the maximum speed without regard to graininess.

Modern thin emulsion fine grain films can safely be developed in a normal (non-fine grain) developer without the risk of undue grain, but for maximum acutance and definition special developers are desirable with such films. These developers also bring out the full film speed.

Degree of Development. The average grain size in most negative materials increases as development progresses. The lower the image contrast produced—i.e., the shorter the development time—the finer the grain. Part of the function of a fine-grain developer is in fact to keep down the contrast. Fine grain development is to some extent a compromise between the lowest negative gamma that will give a good print and the largest grain that can be tolerated. Miniature negatives are therefore best developed to a maximum gamma of 0·7–0·8. Over-development, especially when coupled with over-exposure, greatly increases the grain.

But low-contrast development is not the complete answer to fine grain. While a low-contrast negative will have an image of comparatively fine grain, it needs a hard paper to produce a satisfactory print. On the other hand, a hard paper tends to emphasize the grain of the negative. The most useful fine grain developers are therefore those made up of ingredients which tend to produce reasonably fine grain with reasonably good contrast.

Enlarging Illumination. The ideal enlargers for miniature negatives are those using a light source that is either semi-diffused (opal lamp and condenser) or fully diffused (lamps and diffuser or cold cathode grid). Condenser enlargers with a point source of light tend to emphasize the grain of the negative image, making it much more prominent in the print.

Choice of Enlarging Paper. Contrasty papers accentuate the grain in the negative, soft papers tend to subdue it. However, the final graininess—the combined effect of negative grain and contrast of printing paper—does not normally vary a great deal between an under-developed negative printed on a hard paper and a more liberally developed (but not over-developed) negative printed on a normal paper. A negative developed to a moderately low gamma and printed on a hard paper does, however, utilize the film's effective speed better.

The paper surface also affects the graininess of the final image. Smooth surfaced (especially glossy) papers tend to show up the grain, rough surfaced papers tend to lose the image grain in the paper texture. Large prints of considerable magnification are therefore best made on rough paper.

Degree of Enlargement. Obviously the more the negative image is enlarged, the more prominent the grain will be. The photographer who likes to leave plenty of "air" around the

subject gets a smaller image than the one who takes the trouble to arrange the subject in the finder so that it fills the whole of the negative area right up to the margins. The first worker may have to enlarge his negatives up to twice as much as the other, and in consequence get consistently grainier prints in spite of all his fine grain technique. So, where it can be done without prejudice to correct perspective and depth of field, the image of the subject should always occupy the whole of the available negative area.

FINGERPRINT PHOTOGRAPHY. Technique of photographing finger print impressions on a variety of objects and surfaces; widely used in police work to establish the identity of suspects and to obtain and present evidence.

The basis of the use of fingerprints in crime detection is the fact that the ridge pattern of the skin on the fingers of a person is unique and permanent throughout his life.

Like many other branches of photography, fingerprint recording is a specialist job and requires a knowledge of the science of fingerprints by the operator to enable him to produce the result the expert needs to reach his findings.

There are four types of finger impression which it is sometimes necessary to photograph. They are:—

(1) Latent impressions—sometimes invisible to the naked eye.

(2) Moulded impressions—left behind after the fingers have been coated with some substance such as blood.

(3) "Pick-up" impressions—where the ridges of the fingers have picked up dust or powder and left behind the pattern in the dust.

(4) Inked impressions—taken on a form or card for record purposes.

The satisfactory recording, photographically, of a latent fingerprint found at the scene of a crime depends to a large extent on the correct choice of powder used to develop the impression when it is found. For the other types it is usually only a question of choosing the correct film and illumination.

Equipment. The equipment used varies according to the location and article on which the impressions are found. Many are in difficult positions requiring some ingenuity on the part of the operator to get his camera into position.

Where conditions are suitable, a technical double extension camera (stand camera) enables the impression to be recorded in actual size. Special fingerprint cameras have the lens set at a fixed distance from the film and the impression, again to give an actual size image. The format of technical cameras is usually 4 × 5 or $4\frac{3}{4} \times 6\frac{1}{2}$ ins.; fingerprint cameras take $2\frac{1}{4} \times 3\frac{1}{4}$ in. pictures except for one or two specially made instruments which are 4 × 5 ins. or thereabouts. Occasionally 35 mm. cameras are used but are not generally favoured.

Illumination can be by daylight, photoflood, other tungsten light or by flash. The fingerprint camera is normally battery-operated using four built-in bulbs. Some of the specially made instruments use electronic flash.

When dealing with light impressions on a dark background, a camera fitted with a prism or optical mirror can be used. This eliminates some of the intermediate stages in the preparation of the final print. Filters can be of great assistance in rendering the background darker or lighter.

Inked impressions on cards or forms can be copied satisfactorily on a process camera or by means of xerography in the case of good clear impressions.

Materials. As the aim is, in most cases to increase contrast, process film is widely used but panchromatic and orthochromatic films are as popular. For a very weak low contrast mark, a "lith" type material as used in graphic arts may occasionally be used coupled with extreme contrast development. The choice depends to a large extent on the strength of the impression and the colour of the background.

Technique. With a developed (e.g. powder-dusted) latent impression or a moulded or pick-up one, the choice of camera depends very much on where the impression is and what it is on. If a non-portable surface is in the range of the technical camera or fingerprint camera, either can be used. If there is a sequence of impressions or part of a palm, the larger format of the technical camera may be required, to record the whole area on one negative.

The technical camera is set up with the bellows extended to give an image size of 1 : 1. When focusing the camera, the surface on which the impression appears, the lens panel and the focusing screen should, wherever possible, be parallel to avoid distortion. Accurate focusing is essential in view of the shallow depth of field at this extension. On curved surfaces or surfaces which slant away from the camera, a small aperture is necessary to render the whole of the impression sharp.

With daylight, a white card used as a reflector may assist in evening up the illumination when the light is coming from one side only. Portable artificial light sources should be moved into such a position that the image is shown at its best on the focusing screen. On strongly-patterned, but shiny surfaces, the impression may be made visible by deliberately lighting the surface so that the latter reflects glare into the camera lens. The impression then stands out against the glare. Oblique lighting may be necessary to show up certain moulded impressions (such as those found in soft putty) or pick-ups. Flash bulbs should not be too power-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ful and can be used to advantage at an oblique angle. They are to be preferred when dealing with anything like soft putty, as the heat from the photoflood or other lamp may melt the subject.

If it is not possible to record the impression in actual size, some sort of a marker photographed with it provides a guide for future enlarging.

The fingerprint camera is normally hand held, with or without a template in position over the impression to be photographed. At the front of the camera, legs or an enclosed mouth rest against the surface being photographed. Some cameras require a time exposure as their source of illumination is low. In this case the camera must be held perfectly still during the exposure. Modern fingerprint cameras with more powerful light sources permit exposures of 1/30th second or faster at small enough apertures to bring impressions on a curved surface within the available depth of field. Usually both aperture and shutter speed are fixed to yield a correctly exposed picture with a specified light source and film speed.

Impressions revealed by the use of a light powder can be photographed with a camera fitted with a prism or an optical mirror direct on to bromide paper. This gives a print which is right way round but with the tones reversed, i.e. the impression appears dark in colour on a light-coloured background. If several prints are required, then several exposures have to be made. This is simplified by using a special multiple sliding back holding a long narrow piece of bromide paper. This method saves time and material in the production of the prints.

Portable articles on which fingerprints are found are taken from the scene to the studio where better facilities are generally available to deal with them.

The copying of inked impressions from forms or cards is still best done by orthodox photography using any stand, fingerprint or process camera.

Special treatment is required when dealing with mirrors. An impression can be seen on the surface of the glass and another on the silvered back of the mirror and one appears superimposed on the other. A dark powder is used to reveal the impression and a piece of ground glass is placed ground side down on the impression. The mark on the surface of the mirror is clearly visible but the one on the silvering of the mirror cannot be seen. The photograph is then taken in the same way as any other print.

Weak marks on glass can sometimes be dealt with better by illuminating them from behind and photographing them in silhouette against the light.

Impression on a multi-coloured surface are dealt with by using a powder which flouresces under an ultra-violet lamp. Only the flourescing ridges of the pattern are recorded and the colours of the background completely eliminated.

Printing. No matter whether the fingerprint has been revealed with a light-coloured powder or a dark powder the resulting print must show the impression as a dark pattern on a light background. This is to permit comparison of both impressions in the same form (i.e. the fingerprint form with its black inked impression and a photograph showing black impressions on a light base).

Where the fingerprint has been developed by the use of a black powder, all that is required is a straightforward print from the negative on a suitable grade of paper. If a light-coloured powder has been used, a transparency made from the negative serves to produce subsequent prints. The transparency is made by contact printing the negative on to a piece of slow process film with the negative placed upside down in the carrier. A thin-based film (e.g. 3/1000 in.) is used for the negative to minimize any loss of definition due to the two emulsions not being in close contact. The use of a prism or mirror does away with the need to make a transparency or even a negative.

Photographing the impression in actual size in the first instance simplifies subsequent processing, as prints or transparencies can all be made by contact printing.

Contact prints can be made on bromide or contact papers. Many operators prefer the former in the belief that it records more of the range of tones sometimes found in the impression or that it provides a better balance between the weak and the strong areas. H.Sc.

Book: *Photography in Crime Detection*, by J. A. Radley (London).

FINGERPRINTS. To the photographer, fingerprints may be either a nuisance or they may actually form his subject—e.g., in crime detection and police records. In the first place they are to be avoided, in the second, the aim is to get as clean a photographic image of them as possible.

Prevention. When the fingers press on the surface of a sensitized material they may leave behind prints that become visible later. There are three kinds of contamination which may be responsible: grease, perspiration and processing chemicals.

(1) The natural oil on the skin may leave a greasy, water-repellent imprint. This has no effect on a finished negative or print, but if it is left on the surface of the material before it is processed, it prevents the processing solution from acting on the emulsion. If made on an undeveloped negative the result is a light imprint after processing. A greasy fingerprint on the developed negative will hold back the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

fixer and allow the emulsion to get blacker, so the imprint will show as a black mark on the half-tones.

A greasy finger-mark on a print before development will hold back the developer and later show as a white imprint on the half-tones and shadows.

A greasy imprint made on the surface of a print after development and before fixing will blacken over the half-tones where it has been exposed to light but it will remain clear over the highlights. Later, however, if the print is exposed to daylight for any length of time, such imprints will gradually darken and become visible. The remedy here is to wash hands in soap and hot water immediately before a processing session, and then refrain as far as possible from touching the sensitive surfaces. Forceps should always be used for handling prints.

(2) Imprints of another kind are caused by perspiration on the fingers. The moisture is usually slightly acid and, although it is immediately dissolved and rendered harmless by the aqueous processing solutions, it can set up a chemical action with visible consequences if transferred to the surface of a dry negative or print. This type of imprint may appear either white on half-tones and shadows or dark or discoloured on half-tones and highlights. People whose hands tend to perspire unduly should rinse them in water frequently during processing to dilute the dissolved matter in the perspiration. They should avoid handling sensitized materials before processing and use a self-loading spiral tank for developing films.

(3) The fingers can become contaminated by processing chemicals when manipulating plates and prints in the various solutions. The ideal prevention is to use forceps or, if that is impossible, rinse the fingers in clear water before as well as after putting them in the solution.

Contamination can also occur by indirect means—i.e., from touching objects that have been handled on a previous occasion with contaminated fingers—e.g., taps, bottles and stoppers, door-knobs, and particularly towels. This is a further reason for rinsing the fingers immediately after they have been in contact with a solution. For the same reason it is always wise to wash off any dribbles of solution that run down the side of a liquid chemical bottle.

Colour materials also will finger-mark from any of the above causes and the results show equally over all colours, shadows and highlights. The imprint may be black, clear or coloured depending upon the type of material and the stage at which the fingers touch the surface.

Photography. The grease or perspiration that is normally present on the fingers leaves an invisible print on everything it touches. It is possible to render these imprints visible by dusting with a suitable powder. Photographic records of them can then be made. Fingerprint photography forms an important branch of criminal investigation.

Fingerprints taken for police records may later have to be photographed so that they can be projected in enlarged form for comparison with prints found elsewhere. The photographic technique here is simply a matter of making a normal black-and-white record of a clear black on white impression. F.P.

FINLAY, C. L., 18??–1936. English inventor of mosaic screen additive colour photography process: Thames plate (1908) with integral screen, Paget (1913) with separate screen.

FINLAY COLOUR. Additive colour process in which the ruled mosaic screen was separate from the monochrome negative. It had the advantage that copies could be made by normal black-and-white technique and then turned into colour transparencies by binding each copy up with its own colour screen.

See also: *Colour photography: History.*

FIREWORK DISPLAYS. There are two ways of photographing fireworks: with a time exposure, and with an instantaneous exposure.

Fireworks by Themselves. If the camera is set up on a tripod and the shutter is left open, the light of each firework will register on the film from start to finish. The shutter can be closed after a single firework has gone off, or left open to register the pattern left by several. This technique is also effective for photographing the lightning flashes in the course of a thunderstorm after dark.

The most effective way of collecting a number of firework patterns over a period of time is to close the shutter after each principal event and open it just before the next. This prevents the picture from being spoiled by registering minor fireworks and casual light sources. If this method is adopted, the shutter should be operated by a very long cable release so that the operator's arm can rest; waiting for several minutes with the finger at the ready on the shutter release can be very tiring.

Instantaneous Exposure. Short shutter exposures are only possible when the display produces a great volume of light that lasts for some seconds. At such times, very effective pictures can be made of the faces of the spectators or of silhouettes against the light of fireworks or bonfires. This type of subject calls for the maximum speed that can be obtained by combining large lens apertures with high speed pan films, and processing that puts film speed before every other consideration.

Flash. Both flash bulbs and flash powder can be used to improve firework pictures. The use of flash bulbs or electronic flash to light up people in the immediate foreground calls for double

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

exposure technique. The most effective method is to set the camera on a tripod, focus the lens on the foreground, and stop down so far that the picture will be very much under-exposed. This exposure must be made in between fireworks or the trails will be blurred. Open flash is used to save having to reset the shutter for the fireworks.

After making the first exposure at the best moment for recording an interesting foreground, the shutter is closed, the lens refocused on infinity, and the firework trails are taken in the normal way by opening the shutter on B. The resulting picture will show the fireworks exploding in the sky and reproduce enough of the foreground—e.g., the backs of spectators—to give more depth and interest than would normally appear.

Sensitized Material. For all work of this type only the fastest panchromatic films are of any use—particularly as the subjects are largely red, which would not come out on an orthochromatic film.

Most colour materials are fast enough to record the coloured patterns of the fireworks, and the results are frequently enchanting. Here, too, it is worth-while experimenting with flash to record the foreground objects.

When tracing the fireworks upon the film, using a time exposure, an aperture of *f*8 with a film of speed 32 ASA would normally be suitable.

When examining the results, it is as well to remember that this type of subject always gives a disappointing looking negative in black-and-white. The only reliable way of judging whether the negative is worth printing is to print it.

Most firework negatives should be printed on a hard, glossy or lustre surfaced paper so that every trail or spark appears as white as possible.

For those who enjoy using photo tints, firework prints—and lantern slides—offer plenty of scope and the effects have at least a pleasing novelty that even the most hardened purist would hesitate to condemn. L.V.

FISCHER, NICOLAS WOLFGANG, 1782–1850. Austrian Professor of medicine, University of Breslau. Discovered the light sensitivity of silver albuminate and published a pamphlet in 1814 on the action of light on silver chloride. In 1818 he described how to precipitate metallic silver from silver chloride by the action of zinc, a reaction afterwards made use of in the recovery of silver from photographic residues and waste.

FISH. There is no great difficulty involved in photographing river and sea fish under controlled conditions in a suitable glass-sided tank. This may be either a fair-sized tank with a movable glass plate with which the subject can be penned into a narrow space, or the tank itself may be made narrow enough in the first place. A convenient tank for this is 2 feet long by 18 ins. high by as little as 4 ins. in depth.

AQUARIUM SET-UP. The fish is confined to a narrow zone by a sheet of glass in the water. Black paper surrounds the lens to eliminate reflections from aquarium wall. Backgrounds can be set up behind to appear as if they were inside.

When photographing small fish, the lens is generally brought up so close to the subject that there is very little depth of field. Under these conditions, the narrower the tank the better, because fish have a tantalizing habit of keeping beyond the zone of sharp focus if they are allowed the necessary freedom.

The tank must be fitted with the best polished plate glass, front and back, to prevent optical distortion. All stones, sand and water-weed that form the scenery inside the tank must be well washed. Unless this is done, the soil and dirt will be stirred up by the movement of the fish and degrade the quality of the picture. For the same reason, the fish and the water are always allowed to settle for an hour or so before taking any photographs.

Avoiding Reflections. The camera is never set up exactly square with the front of the tank or it would photograph its own reflection as well as the fish. It is moved about 2 ins. to the side so that the lens-subject line is at an angle to the front of the tank. The small shift out of the square-on position makes practically no difference to the focusing of the camera, but it keeps its reflection out of the picture. All other reflections from the front of the camera and its surroundings are cut off by supporting a sheet of dull black paper or fabric opposite the front of the tank and just clear of the camera lens.

These precautions are, however, not necessary if the camera is brought up to the glass so that the lens hood actually touches it.

Fish may be photographed successfully indoors with artificial light. Again care must be taken to arrange the tank and lighting so that no reflections are shown in the glass, for a tank filled with water can act as a very effective mirror. Most of the front reflections may be obviated with a black cloth as already mentioned. Two floodlights set up above the

camera and about 3 feet each side of it give good lighting, but the whole set-up should be carefully examined on the focusing screen before making an exposure. Another method is to place the tank close to a north window, with one floodlight on the opposite side.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Electronic flash or flash bulbs shining down from above the water surface can also be used.

Suitable Subjects. The majority of fresh water fish may be photographed in a tank of the type described above. It is better to choose small specimens; a fish 6 ins. long will make a better picture than one twice the size.

Any scenery included in the tank should be of the type usually associated with the fish to be photographed. When making records of a fish that spends most of its life at the bottom of the stream, for instance, the bottom, with characteristic weeds, should be shown in the picture. If the fish is a surface feeder, there is no need to show the floor of the tank. Since both the front and back of the tank are glass, extra scenery, and particularly the background, can be most conveniently built up outside and if they are thrown slightly out of focus it helps to give a feeling of depth to the picture.

Fish in Aquariums. The photography of the larger sea fish in public aquariums calls for special equipment and facilities not available to the ordinary photographer. A considerable amount of floodlighting is used and special precautions are taken to avoid reflections. Generally, there is an anti-reflection hood extending from the lens right up to the face of the glass, and part of the illumination may be provided by flash bulbs sealed into glass containers submerged with the fish. O.G.P.

See also: *Pets; Underwater photography.*

FISH EYE LENS. Extreme wide-angle lens covering an angle of view of around or nearly 180°. Lenses of this kind can thus take in a horizon-to-horizon view and yield a circular image. This shows appreciable wide-angle distortion (barrel distortion) since the circumference of the image circle with a 180° angle corresponds to a straight line. Only lines going through the centre of the subject field are reproduced straight (but still foreshortened towards the edge of the field).

FISH EYE LENS. This ultra wide angle system covers an angle of view of up to 180 degrees, with considerable distortion near the edges of the field. Usually the image on the film is circular in shape.

To take in the extreme angle, fish-eye lenses have a highly curved protruding front element resembling a fish eye—hence the name. They are used for various kinds of trick photography as well as for recording the complete sky when pointing directly upwards. Fish eye lenses usually have a maximum aperture around *f*8. The extremely short focal length makes focusing unnecessary, since the depth of field covers all distances from infinity down to a few inches. They are available for 35 mm. and occasionally larger still cameras and for cine cameras.

See also: *Lens history; Wide-angle lens.*

FISH GLUE PROCESS. Process in which a photographic image is produced by printing from a negative on to a metal plate coated with a light-sensitive layer of ammonium bichromate dissolved in fish glue. Where the light has acted, the glue is rendered insoluble and the plate is developed by washing away the soluble glue. The image is heat-hardened to form an enamel-like acid resist and the plate is then etched to produce the relief-printing image. The process is used in photo-mechanical reproduction. The plate is subsequently etched to form a relief printing image, the insoluble glue forming a resist. The process is used in photomechanical reproduction.

FIXED FOCUS. On many of the cheaper cameras, there is no focusing movement and the lens is at a fixed distance from the film. With such fixed focus cameras, all objects beyond about 7 feet from the camera are in reasonably sharp focus.

The success of fixed focus relies on the depth of field of the lens. For cheapness, such cameras are fitted with lenses of relatively small aperture and proportionately great depth of field. A typical example would be a 2¼ × 2¼ ins. box camera fitted with a 7·5 cm. lens with a working aperture of *f*11. If such a lens is focused on 23 feet, the depth of field at *f*11 extends from 11½ feet to infinity. In practice the definition would be considered sufficiently good from about 8 feet. It is thus possible to use such a camera for making reasonably good pictures by simply avoiding subjects closer than 8–10 feet. Many cameras of this type can be used closer than this because they are fitted with lenses with a working aperture even smaller than *f*11. Others have a lens of shorter focus—e.g., 5 cm.—with a correspondingly greater depth of field.

Fixed Focus Setting. Any focusing camera can be converted at once into a fixed focus camera for snapshooting by focusing the lens at the hyperfocal distance for the aperture in use. If the lens has a depth of field scale, setting it for

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

fixed focus working simply means adjusting the focus so that the distant limit of the depth of field for the working aperture coincides with the infinity mark. Obviously, the smaller the working aperture, the closer the near limit of the zone of sharp focus to the camera.

By adding supplementary lenses fixed focus cameras can be used for subjects closer to the camera than the near limit of the depth of field.

Technique. Fixed focus makes the camera easy to use and eliminates the risk of getting the subject out of focus. But while it gives a sharp picture of the subject (so long as it is not too close), it also gives a sharp picture of everything else more than 8 feet or so in front of the camera. This general sharpness is sometimes undesirable. It is all very well for a street scene or a landscape. But trouble arises when the real subject of the picture is viewed against an unimportant or ugly background.

How to Subdue the Background. The owner of a focusing camera can deal with the unwanted background by differential focusing. This cannot be done with a fixed focus camera, so the background must be played down in one of the following ways.

By choosing a plain background such as the sky, or a stretch of sand, grass, or snow. In this case the eye has nothing to focus on but the subject, so it no longer tends to wander away from the point.

By shooting from a low viewpoint. This cuts out the competing objects near the subject and shows it against more distant things which may be lighter in tone and may also be out of focus. Best of all, it may show the subject against the plain blue tone of the sky.

By choosing a contrasting background. A light-toned subject will stand out if it is photographed against a dark-toned background or an area in shadow. In the same way, a dark subject will stand out from a light-toned background.

By swinging the camera. If the camera follows a subject that is moving across the line of view, the subject will be sharp and the background blurred.

By using flash. So long as the background is considerably farther away from the camera than the subject, it will be too dark to attract attention. This method can only be applied in poor light, and it works only if the background itself is comparatively dark in tone. F.P.

FIXING

When negatives or prints have been developed, they should be given a thorough rinse in water or a stop bath. This is to remove or neutralize the surplus developer on the emulsion. They must then be fixed.

THEORY

Fixing is the part of the photographic process in which the unexposed and unreduced silver halide is removed to render the image stable in white light and also to remove the turbidity. This is done by dissolving the silver halide in a solution of a substance that can form soluble silver salts. A wide range of substances is available ranging from cyanides, and thiocyanates, which act quickly, to sulphite and a strong solution of potassium bromide, which are slowest in action. For general purposes sodium thiosulphate (hypo) is the most effective agent.

When silver halides dissolve in thiosulphate solutions they form a series of silver-thiosulphates $Na_x\ Ag_y\ (S_2O_3)_{(x+y)/2}$ according to the conditions. Only two complexes are important in ordinary fixation; in both these $y = 1$ and x is either 3 or 5. When the hypo concentration is below 25 per cent, $x = 3$. Above 50 per cent, conditions favour $x = 5$. Between these ranges, both forms will be present in substantial proportions.

It is better to fix in baths of low silver content because this favours the more rapid removal of the silver-thiosulphate complexes in the subsequent washing. These conditions are usually achieved in practice by fixing in two consecutive baths.

It is undesirable for most purposes to use a plain hypo solution for fixing, especially if the films or plate are transferred direct from the developer to the fixer, because the developer will continue to act in the presence of the fixer. This often results in the formation of a dichroic silver deposit as a stain. This trouble can be avoided by using an acid fixing bath.

The addition of an acid, even one as weak as acetic acid, to a solution of sodium thiosulphate, causes decomposition and the deposition of sulphur. This decomposition can be avoided by having bisulphite present. A simple acid fixer can be compounded from sodium thiosulphate and sodium bisulphite (or potassium metabisulphite). Fixers can be acidified with acetic acid or by acid sulphates (e.g., alum) after adding sulphite or bisulphite.

It is equally essential after fixing to wash negatives and prints thoroughly before drying them. This is to remove the products of fixing that, if remaining, would affect the permanence of the image. G.I.P.L.

Stabilization. The silver-thiosulphate complexes formed with sodium are still sensitive to light, though far less so than the original silver halides. That is why they must be removed from the emulsion. It is, however, also possible to convert the silver salts into complexes which are virtually insensitive to light and thus sufficiently stable to remain in the emulsion.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The advantage of such stabilizing agents is that the fixing process can be very greatly shortened—to a few seconds under favourable conditions—and subsequent washing becomes unnecessary. Suitable complexes for this purpose are formed with agents like thiourea and its derivatives, certain thiocyanates and a number of other substances.

An image stabilized in this way is not as permanent as a properly fixed image. Prolonged action of light and of heat (especially in the presence of moisture) will cause eventual decomposition and deposition of silver to form stains. For that reason stabilization is of particular use in document copying where copies are normally stored in conditions of darkness and are mostly needed for short-term use. A stabilized image can be made fully permanent by refixing—possibly at a more convenient time than the original occasion of copying and processing—in a normal fixing bath.

FIXING NEGATIVES

It is specially important for negatives to be completely fixed because a spoiled negative cannot be replaced and many types of after-treatment will ruin a negative in which there are still traces of silver salts.

Sodium thiosulphate or hypo is the most common fixing agent. Certain other chemicals may be added to the fixing bath to prevent staining, to harden the gelatin, or fulfil some purpose other than fixing.

Acid Fixers. The presence of an acid in the fixing bath ends the process of development at once by neutralizing any alkali carried over from the developer. This prevents the developer from continuing to act locally and form stains on the negative during fixation.

As most acids by themselves decompose sodium thiosulphate, sodium sulphite must also be present to act as a preservative. The same purpose is served by using a bisulphite as the acid salt.

The simplest type of formula is that for bisulphite acid fixing bath:

Sodium thiosulphate	8–12 ounces	200–300 grams
Sodium bisulphite (or potassium metabisulphite)	1 ounce	25 grams
Water to make ...	40 ounces	1,000 c.cm.

This can be made up as (A), a 50 per cent stock solution of sodium thiosulphate, and (B), a 10 per cent stock solution of potassium metabisulphite. For use, two parts of A are mixed with one of B.

A solution containing 5 per cent sodium sulphite and 1·5 per cent concentrated sulphuric acid can be used instead of the potassium metabisulphite stock solution.

Another alternative for the acid stock solution is 10 per cent sodium sulphite with 4 per cent of acetic acid added. This solution is mixed with an equal volume of water and added to the same amount of 50 per cent hypo solution.

In all cases (including acid hardening fixers) the solutions must be mixed cold.

Acid Hardening Fixers. Hardening fixers use either chrome alum or potash alum as hardening agent. The former has the greater hardening power, but the latter keeps better.

The formula for chrome alum acid hardening fixer is:

Stock solution A.		
Sodium thiosulphate (hypo)	24 ounces	600 grams
Potassium metabisulphite ...	2 ounces	50 grams
Water to make	40 ounces	1,000 c.cm.
Stock solution B.		
Chrome alum	1 ounce	25 grams
Water to make	40 ounces	1,000 c.cm.

Equal parts of A and B are mixed just before use. The solution will not keep longer than a day or two.

The formula for potash alum acid hardening fixer is:

Stock solution A.		
Sodium thiosulphate (hypo)	12 ounces	300 grams
Water to make	40 ounces	1,000 c.cm.
Stock solution B.		
Sodium sulphite, anhydrous	3 ounces	75 grams
Glacial acetic acid	2½ ounces	63 c.cm.
Boric acid	1½ ounces	38 grams
Potash alum	3 ounces	75 grams
Water to make	40 ounces	1,000 c.cm.

For use, 3 parts of A are mixed with 1 part of B.

With acid and acid hardening fixing baths it is safe to expose the material to white light as soon as the fixer has started to act, as development is arrested almost at once. But it is never wise to subject unfixed material to strong light for long because it slows down fixation and the action of the light may deposit silver on the emulsion as a thin fog.

Rate of Fixing. The speed with which a fixing bath acts depends on: the sodium thiosulphate concentration, the exhaustion of the solution, the negative material, and the temperature of the solution.

The rate of fixing increases with increasing sodium thiosulphate concentration up to a maximum strength of about 35–40 per cent.

Above that the gain in fixing speed with increasing concentration is less significant, and 30 per cent is a convenient optimum concentration.

The presence of certain other chemicals decreases the fixing rate. Acid fixers and acid hardening fixers work slower than plain solutions containing the same amount of sodium thiosulphate.

As the solution becomes exhausted, the thiosulphate concentration, and thus the fixing speed, decreases. Some of the silver compounds, particularly iodide, in a partly exhausted fixing bath also slow down the action of the bath.

CC-0. Agamnigam Digital Preservation Foundation India

The fixing time also depends to some extent on the negative material. Thick emulsions—particularly double coated ones—contain more silver bromide than thin ones, and take longer to fix. Many high speed emulsions contain a proportion of silver iodide, which is much less soluble than silver bromide, and consequently takes longer to fix. For the same reason, when the silver bromide is converted into silver iodide as in physical development, fixing takes a longer time than usual.

As a rule, papers fix very rapidly. This is because the emulsion layer is thinner and also because, in the case of chloride and chlorobromide papers, the emulsion contains silver chloride which is much more soluble than silver bromide.

The effect of temperature on the fixer is the same as on all other solutions: the warmer the bath, the quicker it acts. At high temperatures a hardening fixer is essential.

For really rapid fixing there are special high speed fixing baths.

Exhaustion of the Fixer. The area of negative material that can be fixed in a given volume of fixing solution is mostly limited by accumulation of iodide and dilution, caused by water carried over by the negative.

Both these effects slow down the fixing rate. In addition the increasing concentration of silver compounds makes fixation progressively difficult, until the point is reached when the material cannot be completely fixed even if the bath is replenished by adding sodium thiosulphate. The high silver content of exhausted fixing baths also leads to staining of materials.

EXHAUSTION OF FIXING BATH

Negative Size in.	cm.	Number of Negatives per 40 ounces (1,000 c.cm.)
1 × 1¼	2·4 × 3·6	1,000
1¼ × 1⅝	3 × 4	1,000
1⅝ × 2½ (V.P.)	4 × 6·5	480
2¼ × 2¼	6 × 6	360
2¼ × 3¼	6 × 9	240
2½ × 4¼	6·5 × 11	180
3¼ × 4¼ (¼-plate)	9 × 12	140
3½ × 5½ (postcard)	9·5 × 14	100
4¾ × 6½ (½-plate)	12 × 16	75
6½ × 8½ (whole plate)	16 × 22	40
8 × 10	20 × 25	30

Film Size or Number	Number of rolls per 40 ounces (1,000 c.cm.)
35 mm. film, 18–20 exposures	60
35 mm. film, 36 exposures	30
No. 828 or 888 (Bantam) rolls	100
Standard No. 27 or 127 (V.P.) rolls	60
Standard No. 20, 120, 62, 620, or Z20 rolls	30
Standard No. 16, 116, 616, or Z16 rolls	20

The acid in an acid fixing bath is gradually neutralized by the developer, which is normally alkaline, carried over in the emulsion of the negative. This will happen sooner when the intermediate rinse is not as thorough as it should be. If the acid in the fixing bath is exhausted before the fixer its action can be restored by adding further acid stock solution.

The number of films or plates that can be fixed in a given quantity of fixer depends finally on the type of the negative material, and on the amount of silver bromide left behind in the emulsion after exposure and development. Thin emulsions films and dense negatives will exhaust the bath less than under-exposed and under-developed negatives where a lot of unused silver bromide remains to be dissolved away.

As a maximum, 40 ounces of fixing solution containing 25 per cent of sodium thiosulphate will fix about 2400 square inches of material (about 1·5 square metres per 1000 c.cm.).

This is given in the tables above in terms of the number of actual negatives that the bath will fix.

Testing for Exhaustion. The speed with which the milkiness of the negative clears gives some indication of the approach of exhaustion. When the clearing time is more than three times as long as with the fresh bath, the solution is best thrown away.

A more exact test is to add about 20 minims (1 c.cm.) of 5 per cent potassium iodide solution to 1 ounce (25 c.cm.) of the fixing bath. If the solution goes cloudy and does not clear on shaking, the fixer is exhausted.

The acidity of the solution can be checked by dipping a piece of blue litmus paper into it. The litmus paper will turn red immediately if the bath is sufficiently acid.

Keeping Properties. Freshly mixed fixing solution will keep almost indefinitely; fixing baths are not exhausted by storage as are developers. In a partly exhausted fixing bath, especially if it is left exposed to light, the silver compounds gradually decompose, forming a blackish sludge of silver. If the acidity is low, a white deposit of aluminium hydroxide may also form from the potash alum present. All these precipitates should be filtered off before use.

Hardening fixers with chrome alum lose their hardening properties within 1–2 days.

Two-Bath Fixing. To guarantee thorough fixation, the normal fixing bath may be followed by a freshly made up bath of the same solution. This second solution removes any last traces of silver salts that may be left in the emulsion when the first bath nears exhaustion, The second fixer stays practically fresh all the time.

When the first bath is thrown away, the second one takes its place, and a fresh second bath is made up. This system uses no more

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

fixer than the single bath method, but it cuts out the risk of incomplete fixation.

High Speed Fixing. As a quick fixer for negatives, ammonium thiosulphate may be used instead of the sodium compound. In practice this is often done by adding 1 part of ammonium chloride (sal-ammoniac) for every 5–7 parts of sodium thiosulphate contained in the solution. The chloride attacks stainless steel, however, in which case ammonium sulphate may be used instead.

Such fixing baths act in about one-quarter to one-half the time needed with normal fixing solutions but they are said to affect the permanence of the silver image.

Ammonium thiosulphate is nowadays widely used in commercial rapid fixing baths. A suitable formula is:

Ammonium thiosulphate	8	ounces	200	grams
Sodium sulphite, anhydrous	265	grains	15	grams
Acetic acid, 28%	1½	ounces	55	c.cm.
Boric acid	130	grains	7·5	grams
Potassium alum	265	grains	25	grams
Water to make	40	ounces	1,000	c.cm.

The chemicals are dissolved in the order listed in about three-quarters of the final volume of water.

Commercial rapid fixing baths frequently are sold in two stock solutions, one containing the ammonium thiosulphate and the other the sulphite and hardening agent.

A 40 per cent ammonium thiocyanate solution containing 5 per cent formalin may be used. This will fix in about half a minute and even less if it is used hot (up to 120°F. or 50°C.). During the very short immersion times the gelatin is not likely to soften appreciably.

The high fixing rate of ammonium thiocyanate makes it suitable for low temperature processing. The solution has a very low freezing point and it takes only a few minutes to fix even below 32°F. (0°C.).

The use of a small proportion of thiosulphate with thiocyanate fixers helps to stabilize the images if not washed after clearing.

Potassium cyanide is another chemical with rapid fixing properties but it is rarely used because it is very poisonous. It has the added disadvantage of attacking the silver image and acting like a weak negative reducer.

FIXING PRINTS

Fixing is as necessary for prints as for negatives—i.e., it removes unused silver compounds still present in the print after development. These silver compounds would in time tend to discolour and mar the print. Thorough fixing is also important if the print is to be toned later.

Fixers. The commonest fixing bath for prints is an acid fixer containing sodium thiosulphate (hypo), and an acid, together with sodium sulphite or an acid salt like potassium metabisulphite. The acid immediately neutralizes any alkali carried over from the developer, particularly if a plain water rinse is used instead of an acid stop bath. It arrests the action of the developer and so prevents stains. It also lengthens the useful life of the fixer.

The formula given for negatives may be used, but only half the amount of sodium thiosulphate is necessary for prints.

Prints should never be fixed in a bath which has been used for negatives. Such a fixer may contain enough silver salts to stain prints, even when it has no obvious effect on films or plates. There is also the risk that the prints will be stained by backing dye dissolved from the back of films or plates.

Acid hardening fixers are not usually necessary for prints; the gelatin layer of printing papers is not as sensitive to temperature changes or physical injury as the emulsion of a film or plate. A hardening fixer may, however, be advisable if the prints are to be hot glazed. In that case the acid hardening fixers for negatives are suitable, but at half strength.

Fixing Time. The usual time necessary for completely fixing chloride contact papers is about one minute, and for chlorobromide and bromide papers about two minutes, all at 65–70°F. (18–21°C.). When the bath is nearly exhausted, fixing may take two or three times as long.

When prints are left in a fresh acid fixing bath, particularly if it is strongly acid, the solution may in time dissolve away some of the fainter highlight detail. And after prolonged fixing the paper fibre absorbs acid, which subsequent washing may not remove completely. This acid can in time attack the silver image.

Prints should therefore not stay in the fixing bath for longer than about ten minutes.

Two-Bath Fixing. As a safeguard against incomplete fixing, two similar fixing baths may be used. The first bath does the main work of fixing, and the second removes any traces of silver salts left in the emulsion. The first bath gets exhausted in the normal time, while the second stays fresh much longer.

When the first bath is exhausted, it is thrown away; its place is taken by the second bath, and a new second bath is made up.

The amount of fixing salts used up is no more than for a single fixing bath, but the two baths ensure complete fixing, even when the first bath is nearly exhausted.

Rapid Fixing. The fixing time of prints is already very short, so the special high-speed fixers used for negatives are rarely needed for normal photography.

The only rapid fixer of practical importance for prints is ammonium thiosulphate. It may be used as a 20 per cent solution with 3 per cent potassium metabisulphite added. Alternatively, it can be made by adding ammonium chloride to a normal acid fixing bath (1 part to every 6 parts of sodium thiosulphate in the fixer).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

At normal processing temperatures, this solution will fix prints in about 15–20 seconds.

Exhaustion. During fixing, the silver salts removed from the prints accumulate in the fixing bath. With print fixers, the concentration of silver salts usually becomes too great to permit complete fixation before all the thiosulphate in the bath is actually used up. This is why nothing much is gained by using print fixers as concentrated as negative fixers; they would still stop working after about the same number of prints.

Print fixers should never be overworked. They may still appear to act satisfactorily, when they are in fact spent. A fresh fixing bath is particularly essential for print permanence.

The number of prints which 1,000 c.cm. or about 40 ounces of fixer containing 20–25 per cent sodium thiosulphate will fix is approximately the same as the number of negatives. The actual work done by the fixing bath is less, because printing papers contain less silver than negative materials. But the amount of dissolved silver which the bath can contain and still work satisfactorily is also lower.

The keeping qualities of print fixers are much the same as those of negative fixers.

Tests for Fixing and Exhaustion. Chloride and cream-tinted bromide papers do not change colour in the fixing bath. Ordinary bromide prints turn from pale yellow to white. This, however, is not a complete guide for fixing.

A better test is to drain and wash a print after fixing, and touch one corner with a crystal of sodium sulphide (or place a small drop of 10 per cent sodium sulphide solution on it). If the spot tested goes brown, the print still contains silver salts and is not completely fixed. If the test gives a brown stain, even after prolonged fixing (5 minutes or more), the fixing bath is exhausted.

The fixing bath itself may be tested directly by the potassium iodide method, while blue litmus paper will check acidity. L.A.M.

FIZEAU, HIPPOLYTE LOUIS, 1819–96. French physicist. Invented gold toning of daguerreotypes in 1840. Inventor of a very successful process of etching daguerreotypes for mechanical printing (1841). Studied (1844, with Foucault) the action of various light sources and of the spectrum on daguerreotype plates and found reciprocity law failures. Took first pictures of the sun on daguerreotype (1845, with Foucault).

FLARE. Bright patch (sometimes also a ring or other irregular pattern) on the print caused by strong light reflections inside the lens. The light may be any bright source inside or on the edge of the picture area, or even a bright rim on the edge of the lens mount or hood.

All lenses tend to form flare spots, although by good design the worst of them can be made to fall outside the limits of the negative normally covered by the lens.

Almost every camera lens will form one or more flare spots if it is pointed towards a light source. These spots show up on the focusing screen and it is a good plan to study the performance of a lens in this way for those occasions when the picture area includes a light source. The quickest way of making such a check is to set the camera up in the darkroom in front of a lighted candle. The position of the flare is noted as the lens is aimed directly at the flame and also to each side of it. It is often possible to arrange the picture so that the flare falls on a light area of the subject.

The position of flare on the viewing screen of a twin lens reflex is no guide to the position of the flare formed by the taking lens. With such cameras, and all cameras without focusing screens, it is necessary to open the back and examine the actual image formed by the taking lens on an improvised screen.

Coating the lens greatly reduces the tendency to form flare.

FLASH BULB

Flash bulbs are artificial light sources which generate light by the rapid combustion of certain metals in oxygen. The whole process takes place inside a glass bulb resembling an electric light bulb and yields a short but intense flash of light. The bulb is fired electrically, and can be used once only. Flash bulbs are therefore sometimes described as "expendable flashes".

History. The first forerunner of the flash bulb was a magnesium lamp by Chauffour in 1893, which electrically fired magnesium ribbon in a glass bulb filled with oxygen. It was designed exclusively for underwater photography. The first flash bulb proper was invented by Vierkötter in 1925 and consisted of a charge of flash powder inside a light bulb fired by a filament covered with magnesium powder. The combustion took place in a vacuum and the bulb gave a light output of over 100,000 lumen

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

seconds. In 1925, Vierkötter produced an improved version filled with low pressure oxygen. In 1929, Ostermeier made the first commercial flash bulb (Vacublitz) filled with aluminium foil. These were marketed in Germany. In 1934, Phillips produced the first wire filled flash bulbs in Holland. Foil- and wire-filled bulbs began to be made in America under licence in 1930 and 1936 respectively where they were soon produced in far greater numbers than they ever had been in Europe.

Construction. The flash bulb consists of a glass envelope shaped like an electric light bulb the end of which carries two electrical contacts.

Inside the bulb, the contacts are joined to a thin wire filament covered with a primer of explosive paste. The rest of the envelope is filled with a loose mass of fine aluminium wire in an atmosphere of oxygen at a reduced pressure.

When a battery is connected across the terminals, a current flows through the filament which becomes incandescent (burning out almost immediately), and ignites the explosive primer. This in turn ignites the aluminium foil or wire, which burns, generating a flash of intense light.

Modern ultra-small flash bulbs use zirconium wire filling, providing the same light output from a smaller quantity of wire. At one time flash bulbs also used to be filled with aluminium foil or with an extra large quantity of primer paste and no wire at all.

The electrical current to fire the bulb is generally derived directly or indirectly from a dry battery. The minimum voltage required is 3 volts, and the maximum with most bulbs is 30 volts (as supplied by a battery-capacitor unit).

Certain large bulbs are designed to be fired from 110 or 250 volt mains, but unless this is specially stated on the package, mains firing can be very dangerous. Where a bulb is designed for mains firing, it must be connected directly to the supply, and not wired through a synchronizer or synchronized shutter.

The usual way of firing bulbs in present-day flash guns is by a battery-capacitor circuit, where a 15 to 30 volt battery charges up a capacitor which in turn discharges through the flash bulb on closing the firing circuit. Such a capacitor can also fire several bulbs (usually up to three or four) which are generally connected in series—wired so that the current passes through one bulb after the other. To fire larger numbers of bulbs booster boxes are sometimes used, employing a high tension battery of 90 to 300 volts; this can then fire several dozen flash bulbs at a time.

Low voltage batteries can also be used for direct firing, but are very rarely used nowadays, since the synchronizing reliability depends very much on the freshness of the batteries.

Flash bulbs can also be fired without electrical connexions at all, simply by being placed very close to another bulb fired in the normal way. In this case the light energy of the first flash sets off the combustion in the second bulb.

Characteristics. Flash bulbs differ mainly in: the amount of light they give, the time they take to light up, the duration of the flash and the colour of the light. Standard information on each of these points is therefore given with each flash bulb. It may be given in the form of a graph showing the variation of light intensity with time, from the instant when the firing circuit is closed to the end of the flash.

Peak brightness defines the maximum light flux in lumens when the flash is at its brightest, and corresponds to the highest point or peak of the graph. A small bulb may have peak illumination of 500,000 lumens, while large bulbs go up to 6 million lumens.

FLASH BULB TYPES. Left: *Large bulb with E.S. cap for professional use.* Centre left: *Glass base (capless) miniature bulb,* European type. Centre: *Small bulb with S.C.C. cap, usually of focal plane type.* Centre right: *Ultra-miniature all glass capless bulb* (American type). Right: *Miniature American bulb with metal cap. All the bulbs are shown approximately two-thirds natural size except fo the large E.S. capped bulb which is half natural size. FLASH CURVES. Left: *The data obtainable from a flash curve are:* A, *peak intensity;* B, *half-peak intensity;* C, *half-peak duration;* D, *half-peak delay;* E, *peak delay;* F, *total duration.* Right: *The typical curves represent:* G, *medium class M bulb;* H, *small class M wire-filled bulb;* J, *large class S bulb;* K, *focal plane bulb.*

The amount of light (as distinct from its intensity) that a bulb yields is measured in lumen-seconds. This depends both on the intensity and the duration of the flash and determines the exposure that the flash produces on the photographic material. Large bulbs have a high light output (over 100,000 lumen seconds), while small bulbs may provide as little as 5,000 lumen-seconds. The same total light output may be generated by either a very intense flash of comparatively short duration, or a less intense flash of longer duration.

In terms of the flash graph, the total light output is the area below the curve.

With most flash bulbs the light intensity rises up to a definite peak and then falls away again. Photographically, the useful part of the flash occurs while it is above half its maximum intensity. The half-peak duration extends from the instant when the curve first rises to half its peak level to the instant when it falls back to the same level again.

The half-peak duration may be quite short—e.g., 5 milliseconds (1/200 second)—or as long as 50 milliseconds (1/20 second).

The half-peak duration does not give any idea of the shape of the peak of the curve. Above the half-peak the flash may rise to its full brightness in a sharp point and immediately fall off again, or it may remain fairly level at a lower value. The latter type of flash is required for focal plane shutter synchronization.

The fact that the flash takes a little time to reach its full brilliance after firing must be allowed for in synchronization. The actual time the flash takes to develop is known as the firing delay or time lag; it can be measured either to the peak or to the first half-peak point, and stated as a peak delay or a half-peak delay. With bulbs yielding a very short flash, the peak is more easily timed, while the half-peak delay only is significant with long-flash bulbs.

Most wire-filled flash bulbs have a colour temperature of about 3800°K and therefore need suitable compensating filters when used for colour photography.

Some bulbs are available with a tinted protective lacquer to raise the colour temperature for matching with daylight type colour film. Daylight flash bulbs carry a blue coating and have an effective colour temperature of 6000°K. Blue bulbs are useful for fill-in flash in daylight.

Flash bulbs for amateur photography are made with two kinds of fittings for appropriate flash guns. Both are known as capless bulbs, as distinct from the larger types which have a metal cap. The European capless bulbs have the terminal wires emerging from the glass base on opposite sides; the American A.G. type has a flattened base with the terminals emerging directly from the bottom and bent up in opposite directions.

American miniature bulbs frequently have a metal cap with a centre contact (U.S. miniature or U.S.M.). The cap is here held in the flash gun by a spring that engages a recessed rim at the end. Small focal plane bulbs have a small centre contact bayonet cap (S.C.C.) of 15 mm. diameter. Large size professional flash bulbs have an Edison Screw (E.S.) 27 mm. diameter cap.

Classification. As most flash photography involves the use of synchronized flash, the firing characteristics affecting synchronization are important in selecting the right bulbs for a given job. Flash bulbs are accordingly grouped in several classes.

Class M (Medium) bulbs form the majority on the market. The peak delay is about 18–22 milliseconds. The bulbs are suitable for synchronization with X- synchronized shutters at slow shutter speeds (up to 1/30 second) or with M-synchronized shutters and delayed release synchronizers at all shutter

TYPES OF FLASH BULB

Class S	45–50	1·8–2·5	19–25	30	17–22	E.S.
Small Class FP	7	0·25	17	—	25	S.C.C.
Large Class FP	22	0·5	18	—	45	E.S.

speeds up to 1/500 second. The light output ranges from 5,000 to 75,000 lumen-seconds, and peak intensities from 500,000 to 5,000,000 lumens. The half-peak duration varies from 8–10 milliseconds for the small bulbs to 16 (and occasionally 20) milliseconds for the large. Some bulbs in this class may be extra-small in size. E.S. caps are fitted on most types; most small bulbs are capless.

Class S (Slow) bulbs have as their main feature high light output (around 100,000 lumen-seconds; peak intensity around 5,000,000 lumens) and long firing delay (30 milliseconds to peak). These bulbs are not really intended for synchronization. With most shutters the speed is limited to 1/10 or 1/25 second, but with fully synchronized shutters and adjustable delayed release synchronizers (which can allow for the greater firing delay) faster speeds are possible. At fast speeds however, a lot of the light output of the bulb is wasted, and it is more practical to use a class M bulb of the same peak intensity but shorter duration. The half-peak duration of class S bulbs is about 20 milliseconds. All these bulbs have E.S. caps, and they are the only type of flash bulb that can be fired from a 110 to 250 volt mains supply.

Class FP (Focal Plane) bulbs are specially designed for synchronization with focal plane shutters at all speeds. They are distinguished by a long and fairly flat peak; the light remains reasonably even during the time of travel of the focal plane shutter. The peak intensity (about 500,000 to 2,000,000 lumens) is rather lower relative to the light output (15,000 to 80,000 lumen-seconds) than with class M bulbs of similar size. The half-peak duration is 25–30 milliseconds with the smaller bulbs for miniature cameras, and 45–50 milliseconds with the larger bulbs for focal plane shutters on press cameras. S.C.C. or E.S. caps are fitted.

Special Flash Bulbs. Flash bulbs are also used in high-speed cinematography to provide the intense light necessary for very short periods. Special lamps of this kind exist with a flash duration of over 1½ seconds. This is adequate for most high-speed sequences. For example, one second covers the exposure—at 2,000 frames per second—of 25 feet of film. (In practice, this is a 50 feet load, for the other 25 feet have to run through the camera first while the latter accelerates to this framing speed.)

For longer filming sequences—for example, 6–8 seconds—it is possible to link several such extra long peak bulbs to fire in succession. Provided the flashes are suitably synchronized, the lighting should be steady.

Unusual flash bulbs proposed include discharge-firing types, where the flash is initiated by a spark passing through the primer paste on the terminals to the wire filling between the terminals. This type of bulb has a high internal resistance, no connecting filament, and needs a high voltage but low intensity firing current. Such bulbs are intended for firing by a piezo-electric impulse, in other words a minute current of several hundred volts produced by mechanical impact on crystals of certain substances. Piezo-electric firing systems have been suggested for building into camera shutters; their main merit is that they are compact and need no external current.

Safety Measures. Despite all precautions, a bulb may burst on firing with consequent risk of injury to the people around. So all bulbs are now covered with a layer of cellulose lacquer (clear on clear bulbs, tinted on colour bulbs) to reduce the risk of flying glass splinters.

The most likely cause of bursting is the entry of air into the low-pressure atmosphere of oxygen. Some makes therefore carry an indicator spot inside the bulb. This spot changes colour if any leakage has taken place.

An additional precaution in use is to have a safety screen of wire mesh or transparent plastic in front of the flash bulb when taking portraits and especially pictures of children. Such shields are particularly desirable when the flash is fired at close range. L.A.M.

FLASH CAMERA. Camera type, often of simple box camera construction, incorporating a small flash gun taking miniature flash bulbs. On box cameras of this kind part of the front of the camera body is usually shaped in the form of a metallized reflector with a central socket for the bulb. The camera further takes batteries in a special compartment to fire the bulb, and the firing circuit is wired internally to the shutter.

Miniature (35 mm.) flash cameras follow two main designs. One incorporates a tiny reflector in the space normally taken up (sometimes on alternative versions of the same camera) by an exposure meter. Here an ultra-small flash bulb is pushed in from the top, and the reflector spreads the light just sufficiently to cover the subject field taken in by the camera.

The alternative design has the socket for the flash bulb in the top of the body. This may be covered by a folding flap which on opening also acts as the flash reflector. Alternatively, the reflector may rise up out of the camera top. In either case the light spread is calculated to throw some light directly on the subject and some up at the ceiling for bounce flash.

The power for the firing of the bulb is provided in most cases by one or two pen-light miniature cells which fit into a special camera compartment. One or two cameras use miniature mercury button cells together with a transistor circuit to step up the cell voltage sufficiently to charge a capacitor.

Where the camera has an adjustable lens aperture it can be used over a range of subject distances, according to the guide number of the flash (usually only one type of flash bulb can be used). With cameras where the lens aperture is restricted to one or two settings, the flash distance is similarly restricted.

Special flash cameras for scientific purposes are frequently designed to operate at specific close-up distances. There the proximity of the flash to the lens provides virtually shadowless illumination. Some cameras of this type use a built-in electronic flash unit—occasionally in the form of a ring light surrounding the lens. This type of equipment is finding increasing use in ophthalmic, dental and pathological photography. Here the flash intensity, close-up setting of the camera (with or without supplementary lenses) and the film speed to be used are matched to achieve correctly exposed and fully sharp results at the prescribed setting. L.A.M.

BUILT IN MINIATURE FLASHGUNS. The ultra-small AG1 type flash bulb permits incorporation of flashguns in 35 mm. miniature cameras. The commonest designs are the hinged reflector with the bulb socket in the camera top or in a compartment on the front (top and centre), and the pop-up reflector plus lamp socket (bottom).

FLASH CAPSULE. Now obsolete. Measured quantity of flash powder which used to be supplied in the form of a capsule to plug into a flash gun.

See also: *Flash powder.*

FLASHED OPAL. Glass in the form of a clear sheet with a thin opal coating on one side. It is used as a diffuser in front of the lamps in contact printers and enlargers.

FLASH (ELECTRONIC)

Electronic flash, as used in photography, is produced by an instantaneous electric discharge between two electrodes in a gas-filled glass bulb (called a tube).

In practice, the electrical energy for the discharge is stored in a condenser (otherwise known as a capacitor).

The main components of an electronic flash unit are therefore: the power supply, the capacitor, the triggering circuit, and the flash tube itself usually with a reflector.

The power supply in portable equipment is often packed with the capacitor in one unit—the power pack. The triggering circuit and the flash tube make a second unit which may resemble a flash gun in appearance.

Miniature portable electronic flash units contain everything in a single lampholder, including the power supply, capacitor and flash tube. The smallest types are compact enough to fit into the accessory shoe of a miniature camera like a normal flash gun for bulbs.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The Power Supply. The electric current used to charge the capacitor must be a direct current of the appropriate voltage for the tube (usually around 2000 volts, depending on the type, but often as low as 250 volts or less with low-voltage tubes).

Direct current at a suitable voltage can rarely be produced directly; it is mostly derived from a comparatively low voltage source, and stepped up. The following systems are in use:

(1) Accumulator with vibrator, transformer and rectifier circuit; or with transistor system.

(2) A.C. mains with transformer and rectifier.

(3) High-tension drybatteries.

Accumulator Units. An accumulator (usually of the lead-acid or nickel-cadmium type) provides an efficient power supply, and is reasonably portable. Its main disadvantage is its weight, to which has to be added the weight of the transformer and other units required with it.

An advantage is that accumulators can be recharged fairly easily. Some electronic flash units utilize very small light-weight accumulators and incorporate a charging circuit. The number of flashes obtainable from an accumulator charge is small in that case, but the unit is intended for frequent recharging by simply plugging it into the mains supply.

The accumulator provides current at about 2–6 volts, according to the number of cells used. To convert this into the necessary high voltage involves three operations:

(1) A vibrator or make-and-break circuit (similar in principle to the circuit of an electric bell or buzzer) converts the continuous direct current into an intermittent one.

(2) The low-voltage intermittent current is converted into a high-voltage alternating current in the following way. The intermittent current is fed into the primary winding of a transformer where the interruptions in its flow produce a fluctuating magnetic field. This induces an alternating current in the secondary winding of the transformer. The value of the induced voltage depends on the ratio of the number of turns in each winding. So the transformer can be made to convert the low-voltage intermittent current into alternating current at any desired voltage.

MAINS POWER PACK. The A.C. mains supply is rectified by a doubling circuit and charges the power capacitor. An automatic safety switch discharges the capacitor when the unit is opened. E, earth. L, live. N, neutral. T, trigger lead.

(3) A rectifier converts the high-voltage alternating current (which is useless for charging a capacitor) into a high-voltage direct current. The rectifier may be of the radio valve type or a metal rectifier. In either case it acts by letting the current pass in only one direction; a simple rectifier thus yields an intermittent direct current. With a suitable circuit of two rectifiers a smooth current is obtainable.

Modern electronic flash units replace the vibrator circuit and rectifier with a transistor system, saving weight and bulk.

Mains Supply. High-powered electronic flash units have a heavy current consumption and accumulator operation would be inconvenient. As these units do not have to be portable, they can be supplied directly from the mains.

Generally the mains voltage is still too low and has to be stepped up. With A.C. mains this requires a transformer and a rectifier, while with D.C. mains a vibrator or transistor—as for an accumulator unit—is also necessary.

Units employing low-voltage flash tubes can be charged directly from a D.C. mains supply, or through a rectifier from an A.C. supply. With alternating current, two rectifiers can be connected in a doubling circuit which doubles the voltage output, and can be made to yield 500 volts from a 250 volt mains supply.

Frequently portable units also permit mains operation, usually as an alternative to battery operation. In most cases the unit incorporates a charging circuit which automatically recharges the accumulator when connected to the mains.

High-tension Batteries. These charge the capacitor directly through a resistor, and need neither vibrator, transformer nor rectifier. The weight of the power pack is therefore much lower, especially when it consists of light-weight hearing aid batteries, but operation is more expensive as the batteries have to be replaced completely. High-tension operation is more suitable for low-voltage tubes (250-500 volts although it has been used up to 800 volts) since the bulk of the batteries required to produce higher voltages would be too great.

The Capacitor. This stores electric power supplied by the transformer and rectifier or by the high-tension battery.

In principle, a capacitor consists of two layers of metal foil each connected to a terminal of the power supply and separated by a thin layer of insulating material.

The amount of electrical energy that a capacitor will store depends only on its capacity

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

and not on the strength of the charging current. So a small current can be made to charge up a large capacitor with a considerable amount of electrical energy. The intense flash is the result of discharging in a fraction of a second all the electrical energy that has built up inside the capacitor over the whole of the charging period. This, of course is the basic principle.

Capacitors are rated in microfarads according to their capacity, and in volts D.C. according to their maximum working voltage. Electronic flash unit capacitors range from 30 to 200 microfarads, at working voltages up to 2500 volts. The plates of these capacitors are usually aluminium foil, separated by thin oiled-paper insulation. Such capacitors are known as paper-type capacitors.

An alternative type of capacitor uses a liquid electrolyte (generally a solution of an alkali). Electrolytic capacitors are smaller and cheaper for the same capacity than the paper-oil type, but are not as durable. Moreover, an electrolytic capacitor must always be connected into the circuit with its + pole wired to the + pole of the charging circuit; reversing the polarity of the capacitor ruins it. Paper insulated capacitors can be connected without regard to polarity.

Electrolytic capacitors are suitable only for low-voltage flash tubes and are rated up to 500 volts with capacities of up to 600 microfarads for electronic flash units.

Electrolytic capacitors tend to lose their storage ability when left lying unused for long periods. They then become "depolarized" and have to be reformed by being kept under charge for several hours. The main result of a partially depolarized capacitor is reduced capacity and greater leakage rate, and hence lower available flash energy. If an electronic flash unit using electrolytic capacitors is in only intermittent use, it is advisable to keep the capacitor under charge for about one quarter hour once a week.

H.T. BATTERY POWER PACK. A high-tension battery charges the power capacitor directly through a resistor, controlled by a two-way charge-discharge switch. T, trigger lead.

Wiring of capacitors follows the same principle as wiring of batteries. Connecting a number in series proportionately increases the voltage they can carry but only with the capacity of a single unit; connecting them in parallel increases their total effective capacity, but only for the voltage of a single unit.

Charging Time. The capacitor takes some time to charge up—on commercial electronic flash units from 5 to 15 seconds. The charging time depends both on the size of the capacitor, and on the charging current. The latter is determined by the resistance of the charging circuit.

Small sets powered by high-tension batteries with small capacitors charge up quickly; large units with big capacitors and transformer circuits take longer.

Leak Resistors. In most electronic flash units the two sides of the capacitor are connected through a high resistance of 1 to 10 megohms. This arrangment is largely a safety measure to prevent accidental shocks as it gradually empties the capacitor it left in a charged condition. The rate of leakage is not sufficient to affect the normal operation of the flash unit.

The leakage current can also be used to indicate the state of the charge on the main capacitor, since it is proportional to the charge. For this purpose a micro-ammeter may be connected in series, or a small neon bulb joined in parallel. The latter lights up when the leakage current exceeds a certain value, and thus indicates when the capacitor is charged. Generally this neon bulb is housed in the flash head itself with the tube.

In practice the point at which the neon bulb lights up is somewhat below the maximum capacitor charge. Hence if the capacitor is allowed to charge up for a few seconds longer, the flash obtained is more powerful.

As this may well lead to inconsistent output, better type modern electronic flash units incorporate transistorized automatic charging circuits. These interrupt the charging current to the capacitor when the charge on the latter has reached a certain value, and restart charging when the charge drops below a specified level. On the one hand this arrangement saves battery current in battery portable units when keeping the flash in readiness for use. On the other, it ensures a reasonably constant charging level, and hence light output—for every flash. The automatic charging circuit may also be linked to an audible signal such as a whistling tone which cuts in at the same time as the charging current.

The leak resistor may also act as a potentiometer to provide the triggering current for the flash.

The Flash Tube. This takes the form of a narrow glass tube containing an inert gas at low pressure and with two electrodes sealed into the ends. On applying a suitable high voltage to the electrodes, a luminous discharge takes place through the gas.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The pressure of the gas determines the resistance of the tube and the voltage required for the discharge, while the nature of the gas determines the colour of the light. Most electronic flash tubes contain krypton, xenon, and small quantities of other rare gases, balanced to yield a light approaching daylight in colour.

The tube itself may have various shapes: straight, coiled, or U-shaped. The straight and U-shapes are common for smaller flash units, while the more powerful tubes are of the coiled type. The energy dissipated at the peak of the flash is very great, and the tubes are generally made of quartz or special glass to withstand the strain.

Electronic flash tubes are also made in the form of a ring to encircle the lens to give shadowless illumination, particularly for dental and medical photographs. In such specialized fields it is often an advantage to eliminate shadows so that the tone and colour values of the subject can be studied independently.

Flash Tube Fittings. There are no standardized flash tube fittings as there are standard lamp caps for flash bulbs, since each maker of flash units uses his own way of mounting the tube in the unit. Some tubes are available simply with soldering tags, while others use one or more of the various radio valve bases such as 3-pin, 4-pin or international octal. A few tubes are even made with standard or small Edison screw fittings.

Flash Reflectors. Electronic flash tubes are invariably mounted in a reflector to concentrate the maximum amount of light on the subject. Reflector shapes vary enormously both according to the size of the flash unit and the purpose for which it is intended.

Small portable units have often a trough-shaped reflector with a straight flash tube. This provides the highest light efficiency (important to make up for the comparatively low power of such units) but spreads the light over a comparatively limited angle. Frequently this only just covers the angle of view of a normal camera lens; when used with wide angle-lenses such flash units may only illuminate the centre of the subject area. In any case the flash needs accurate aiming.

Larger portable and semi-professional units often have a reflector of lower efficiency but more even light spread and less harsh illumination. The reflector may with these units be adjustable to provide a narrow or a wide beam of light to choice.

Commercial studio electronic flash units use lamp sets of a great variety of shapes and sizes for broad to narrow floods of light and even highly directional reflectors for spot lighting effects.

Some makers of electronic flash outfits tint the reflector (or the protective plastic screen in front of it) faintly yellow to make the colour quality of the flash match more closely the colour of average daylight when used with daylight type colour films.

FLASH HEAD. The charge from the power capacitor is applied across the tube. Closing the firing switch generates a pulse in the coil which triggers the discharge.

Firing the Flash. The two main methods are: a triggering electrode and a magnetic relay.

Most modern electronic flash units use the triggering electrode, since it is much safer and more convenient in practice.

In this type of circuit the main capacitor is connected permanently across the flash tube terminals. The resistance of the gas in the tube is normally too high to permit a direct discharge. For firing the flash there is a third electrode—usually a coil of wire wound round the outside of the tube. An instantaneous triggering voltage of 5,000 to 10,000 volts applied to this electrode ionizes the gas in the tube, thus lowering its resistance and allowing the capacitor to discharge its energy through the tube in the form of a flash of light.

The triggering voltage is usually supplied by a small induction coil energized by a suitable voltage picked off a potentiometer across the main capacitors. The triggering switch may be the synchronizing contacts inside the camera shutter or a synchronizer or a press button on the flash head, or any type of remote switching device. The whole process of triggering takes a few microseconds and is, from the point of view of synchronization, virtually instantaneous.

An alternative method uses a cold cathode valve to control the triggering current. The triggering voltage is permanently connected to the anode and cathode of the valve and the actual firing impulse is released by a low voltage applied to the grid of the valve. The advantage of this arrangement is that no high-tension current passes through the triggering switch at all, and that a very weak current can trigger the flash. This permits operation by impulses from a microphone or photocell, and is the basis of many automatic triggering methods for complex studio set-ups and also ultra high-speed work.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Relay-fired flash tubes—now virtually obsolete—have no triggering electrode, and the capicitor is not normally connected to the tube. In this case the resistance of the tube is low enough for the discharge to occur the moment the circuit is closed. A magnetic relay, powered by a separate low-voltage battery circuit and controlled by the camera shutter or a synchronizer, is used to close the main switch and connect the capacitor to the flash tube. This system involves a firing delay due to the mechanical movement of the relay and so does not synchronize as accurately as a triggered flash.

Light Output. The light output depends on the energy of the discharge, and electronic flash units are generally rated according to their energy in joules or watt-seconds (the two are numerically equal).

The discharge energy depends on the capacity of the capacitor, and the voltage, and can be calculated from the equation:

$$J = \tfrac{1}{2} \times C \times (kV)^2$$

where J is the energy in joules, C the capacity in microfarads, and kV the voltage in kilovolts.

Thus a discharge from a 66 microfarad capacitor charged at 2500 volts (2·5 kilovolts) would give a flash of $\frac{1}{2} \times 66 \times (2{\cdot}5)^2 = 206$ joules (or watt-seconds). Not all this energy is necessarily converted into light, as there are losses in line resistance, and leakage.

Flash tubes are designed to withstand the energy of a particular intensity of discharge and are rated according to the discharge voltage and power loading they can carry.

The light-output in lumen-seconds depends on the efficiency of the tube and of the discharge circuit in lumens per watt. Generally a 200 joule tube has an output of 7 to 10 lumen-seconds and gives a roughly equivalent exposure to a normal flash bulb of similar output. The effectiveness of the flash unit for exposure purposes depends on the light output, the power, as well as the reflector efficiency. Since electronic flash tubes are usually associated only with the reflector in which they are fitted, it is customary to quote guide numbers for the whole flash unit. These are—unless inflated by advertising claims—a more reliable indication of the performance of a flash unit than the discharge energy in joules or watt seconds. In other words, when two units of say 25 and 35 watt-seconds are compared, the 25 watt-second flash reflector may conceivably be so efficient that the smaller unit actually provides greater illumination on the subject.

ELECTRONIC FLASH CURVE. A: The electronic flash is very brief and intense, with virtually no firing delay. B: By comparison even the fastest flash bulb is very slow in firing with a small peak intensity but considerably longer duration.

There are industrial standards (for example the German standard DIN 19011) which precisely specify the measurement of a guide number for electronic flash units. The method is similar to film speed measurement and involves comparison exposures of a film sample behind a grey scale.

Exposures are made on the one hand to a standard light source and on the other to the flash to be measured. The guide number is calculated from the grey scale steps behind which the film shows, after development, a minimum density of 0.1 above fog.

The main feature of these guide numbers is that they are accurately reproducible and not subject to optimistic advertising claims. The standard lays down a room factor (reflected light from walls indoors) and other details to be taken into account in measurement. The recycling time and the number of flashes obtainable from a set of batteries or an accumulator charge are also the subject of specific measurement methods.

Flash Duration. With normal electronic flash units the duration of the flash varies between 1/300 second and 1/5,000 second. With a 100 joule unit operating at 2,000 volts, it is around 1/3,000 second; portable units of 50 to 60 joules operating at 250 volts have a flash duration of between 1/500 and 1/1,000 second. This is as short as, or shorter than, the shortest exposure time that most normal camera shutters can give. Electronic flash is therefore specially suitable for high-speed action photography, and can arrest most fast movement.

Mathematically, the flash duration can be calculated from the equation:

$$t = C \times R$$

where t = duration in microseconds
C = capacity in microfarads
R = tube resistance in ohms.

The tube resistance is the apparent resistance during the discharge, and is about 5 to 6 ohms for a tube operating at 2000 volts.

Thus a 200 joule tube operating at 2·5 kilovolts (as described before) with a 66 microfarad capacitor would have a flash duration of 400 microseconds, or 1/2,500 second. But the resistance of the wires connecting the capacitor to the tube must also be taken into account.

Other Characteristics. In addition to light output and flash duration the following data

TYPES OF FLASH TUBE

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Type	Joules	Recommended Voltage	Recommended Capacitor (mfd.)	Output Lumen-seconds	Effective Duration seconds
Small low voltage	35–50	200–250	1,000	2,000	1/300
Medium low voltage	75–100	450–500	600	4,000	1/500
Medium voltage	100–200	1,000–1,300	200–400	4,000–8,000	1/1000–1/3000
Small high voltage	100–300	2,500	30–100	4,000–13,000	1/3000–1/5000
Studio	400–1,000	2,500	150–300	18,000–50,000	1/800–1/2000
Large studio	10,000–16,000	3,000–4,000	2,000–3,000	500,000 and over	1/300
Microflash	35–50	7,000–7,500	1–2	1,000	1/1000000

are also of interest in photography.

The firing delay of instantaneous firing discharges is of the order of 20 to 30 microseconds, or about one fiftieth that of the fastest firing (class F) flash bulb. This type of flash is defined as class X flash for purposes of synchronization. With relay-fired units the delay is similar to class F flash—5 to 10 milliseconds.

The peak intensity is proportional to the square of the voltage discharging through the tube. Its practical importance is not very great, since the total light output matters more. The peak intensities of normal flash tubes vary from 10,000,000 to 50,000,000 lumens.

The colour temperature depends on the mixture of the gases in the tube. Strictly speaking, it is not really possible to specify a colour temperature with flash tubes since the spectrum is not a continuous one. For photographic purposes, however, most modern flash tubes behave like a light source with a colour temperature of around 6000°K and are thus suitable for colour photography with daylight type colour films.

Types of Flash Unit. Electronic flash units on the market are classified according to their portability as well as their power supply.

Battery-portable units carry the power source (accumulator and anciliary gear, or high-tension battery) and the capacitor in a power-pack—usually a plastic case with a shoulder-strap. The flash tube and triggering circuit are built into a flash head similar to a normal flash gun which carries the reflector and can be fixed to the camera by the accessory shoe or tripod bush. These units weigh from 2½ to 15 lbs., and have a power loading of 35–200 joules.

Mains-portable units are similar, but are designed for connexion to a mains supply, and are thus not self-contained. Some units provide for alternative battery and mains operation.

Miniature battery units, working from small nickel-cadmium accumulators or hearing aid batteries, combine all components in a single compact unit that fits directly on the camera. Outfits of this kind weigh about 1–2 lbs, and have a power loading of 20 to 35 joules.

Studio electronic flash units nearly always derive their power entirely from the mains supply. They resemble a studio floodlamp unit in appearance, the power pack being built into the base of the lamp stand or into a separate case on wheels. One power pack may supply several lamp units in various combinations. Many of these units incorporate a filament lamp of 100 to 500 watts, to serve as guide light when setting up the lighting scheme. The power may be from 500 to 20,000 joules, 1,000 joule units being the most common type.

Safety Measures. The high voltage of the capacitor charge of most electronic flash units is capable of giving a fatal shock, and special precautions are necessary in handling this type of equipment.

It is unwise at any time to open the case of an electronic flash unit while it is still connected to the mains, or until it has been left disconnected for some minutes. Even then, before doing any repairs or testing, the main terminals of the capacitor should be short-circuited with the blade of a well-insulated screwdriver.

The unit should never be left where it is likely to get wet, or even damp, because the danger of shock from moist surfaces is greatly multiplied. And connecting plugs should never be pulled out, or the tube removed from its holder while the set is switched on.

One built-in safety measure is the leak resistor connected across the main capacitor. This ensures that the charge drains away when the set is not in use. Generally an additional discharge circuit consisting of a resistance of about 5000 ohms is provided and is automatically connected across the capacitor on switching the unit off. This immediately dissipates the charge.

Similar discharge resistors are often fitted to the connecting plugs of the cable from the power pack to the flash holder. Pulling out the plug then automatically discharges the set, ruling out any possibility of shock from the exposed connexions.

All exposed metal parts of a flash unit should be earthed.

Apart from normal photographic flash units, various types of electronic flash have been designed for specialized applications. The most important of these are micro-flash, stroboscopic, and X-ray flash units.

Micro-flash. The duration of an electronic flash is already very brief but by special design it is possible to achieve even shorter flashes for ultra-high-speed photography in such fields as ballistics.

As the flash duration depends largely on the capacity of the main capacitor, micro-flash

units use very small capacitors of the order of 1 to 2 microfarads. The voltage has to be correspondingly high (generally at least 7,500 volts) to yield sufficient light. Even so, micro-flash units rarely exceed 35 to 50 joules, while the flash duration is of the order of one microsecond (1/1,000,000 second).

CC-0. Jangamwadi Math Collection. Digitized by eGangotri

Stroboscopic Flash. If the triggering circuit of a flash unit is permanently closed, the tube will discharge automatically every time the charge on the capacitor reaches a sufficiently high level. The unit will thus flash continuously at a rate depending on the characteristics of the charging circuit.

Units of this type are used for stroboscopic examination of moving objects—e.g., machinery.

The faster the capacitor charges up, the greater the rate of flashing. Stroboscopic units therefore have comparatively small capacitors and a high-output power supply. As the power is generally derived from the mains, this type of flash requires a large transformer and a corresponding charge rectifier.

The flash tube itself must also be specially designed for stroboscopic work, as a normal tube would not stand up to a series of discharges in rapid succession. The flashing rate may be up to several hundred flashes a second.

X-ray Flash. The principle of electronic flash can also be applied to X-ray tubes by passing an instantaneous discharge through the X-ray tube instead of a continuous current. Like a normal electronic flash unit, an X-ray flash unit requires a power supply, a capacitor, and a firing circuit for operation, though the detailed circuits are different. The voltages are up to 200 times as high, while the flash duration is of the order of 1 microsecond. L.A.M.

FLASH EQUIPMENT

In normal flash photography the bulbs are usually fired in a flash holder or flash gun which may be attached to the camera and connected with the shutter by a firing lead.

Originally flash guns were flash holders incorporating a synchronizer. As nowadays all camera shutters are internally synchronized, such synchronizers have disappeared from use, and the terms flash holder and flash gun are used interchangeably.

The basic components of a flash holder are:

(1) A battery case to hold the batteries which fire the flash.

(2) A lamp holder to take the bulb.

(3) A reflector to concentrate the light.

(4) A firing switch or outlet to an external switch to complete the flash circuit.

Many flash holders also incorporate:

(5) A test circuit to test the bulbs and the firing circuit.

(6) A bracket or suitable arrangement for mounting the holder on the camera.

(7) A firing lead and plug to connect to the camera shutter.

Nowadays many flash guns incorporate these features (or at least the first four) in very compact units, sometimes no bigger than a match box.

Battery Cases. Early flash guns used to take two or three 1·5 volt dry cells (to yield a firing voltage of 3 or 4·5 volts) in a comparatively bulky battery case resembling a large pocket torch. Nowadays direct firing by low voltage batteries (which had to yield a high current to be reliable) has given place to battery-capacitor firing, using a small anode battery of 15 to 30 volts and a capacitor. This arrangement is considerably more compact, and is sometimes even built into the camera itself.

The battery may measure as little as $\frac{1}{2} \times \frac{1}{2} \times 1$ in., and is usually of the type used in various kinds of hearing aid. It charges a capacitor (mostly a 50–100 microfarad electrolytic type) which on closing the firing circuit fires the flash bulb.

The advantage of this system is that the charge of the capacitor is constant even when the battery is nearly exhausted, because a failing battery merely takes longer to charge the capacitor. So a capacitor always fires the bulbs reliably. There is no appreciable direct drain on the battery; only enough electricity is used each time for the flash itself, and the current is sufficient to fire several bulbs at once. The battery thus lasts much longer and as a result, battery-capacitor flash guns are rapidly displacing ordinary battery flash guns.

In practice, the charging circuit also incorporates a resistor of several thousand ohms. This increases the charging time to several seconds instead of a fraction of a second, but prevents any sizeable discharge of the battery directly through the bulb. In most battery-capacitor circuits the bulb itself completes the charging circuit so that the capacitor does not charge up until the bulb is inserted.

Since an electrolytic capacitor is used (a paper type of the same capacity would be much too bulky) the battery must always be inserted the same way round. Usually the battery case is marked with appropriate symbols to indicate the position of the + and — poles of the battery as a guide to fitting a new battery.

The battery and capacitor assembly generally take up no more room than two or three cells of a standard battery. It is therefore possible to convert a plain battery model to capacitor operation by making a suitable

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

FLASH GUNS. Top: *The orthodox flash gun contains all the electrical circuit inside a tube which carries the flash bulb socket and the reflector. A flash cable connects the gun to the shutter. The gun is usually joined to the camera by a bracket.* Bottom left: *Many modern guns are small enough to clip into the accessory shoe. The firing connexion is either a flash cable or a contact in the accessory shoe.* Bottom right: *Some flash guns have an arm with bayonet ring for mounting on the finder lens of certain twin-lens reflex cameras.*

insert to hold the battery and capacitor circuit, and loading this into the battery case in place of the normal batteries.

The details of construction will of course depend on the dimensions of the battery case.

Lamp Holders. Amateur flash guns usually take capless glass-base flash bulbs. There are two types: the European one where the glass base is more or less round, and the American (A.G. type) with a rather smaller oblong base. In both cases the terminal wires from the filament inside the flash bulb protrude on opposite sides of the glass base. The two types of bulb cannot normally be used in the same flash gun, especially as the American type capless bulb is designed for ultra-miniature flash guns.

In America miniature metal-capped bulbs are also used (but not the European glass based bulb) and flash guns carry a corresponding lamp holder.

Professional flash guns have one of two types of lamp holder:

(1) To take small centre contact bayonet cap bulbs with a cap diameter of 15 mm. (S.C.C., A.S.C.C., or B15s).

(2) To take Edison screw cap bulbs with a cap diameter of 27 mm. (E.S., or E27).

The S.C.C. lamp holders are intended for the smaller types of focal plane (class FP) bulbs and the E.S. lamp holders for all large professional flash bulbs. The flash guns for the latter are also comparatively larger.

At one time bulbs with S.C.C. cap were the standard amateur flash bulb, and a number of simple flash guns taking this type of bulb still exist. These can be converted to take the European type of glassless bulb with the aid of a simple adaptor.

Adaptors are also available for fitting S.C.C. bulbs into E.S. lamp holders and vice versa.

Most lampholders on flash guns incorporate an ejector to remove the hot fired bulb from the gun without touching it by hand. This is simply a button which bears against the centre of the glass base from underneath, and pushes the lamp out of its fitting when required. On S.C.C. lamp holders the mechanism consists of a spring-loaded contact and a catch which normally retains the bulb in the holder against the thrust of the spring. On pulling aside the catch, the spring-loaded centre contact ejects the bulb.

Reflectors. The flash bulb emits its light in all directions, and if used by itself only about 8 per cent of the light would reach the subject directly. The reflector collects some of the remaining 92 per cent of wasted light and redirects it towards the subject. The reflector is thus of great importance in assessing the effective light of the flash reaching the subject. The simplest types of reflector may utilize about 15 to 20 per cent, and the most efficient type about 60 to 70 per cent. With the same flash bulb in two different reflectors the exposure may thus vary by the equivalent of over two stops. That is one reason why guide numbers for flash exposures as given by bulb manufacturers are necessarily vague and subject to considerable modification in practice.

The efficiency of a reflector depends on its size relative to the flash bulb, as well as its shape and surface.

The larger the reflector, the more light it collects. For the same effect, a large bulb needs a larger reflector than a small bulb.

Amateur flash guns for miniature bulbs usually have a reflector of about 3 inches in diameter, though for higher efficiency a reflector size at least twice as large is better. The smallest guns for the American A.G. capless bulbs have minute reflectors only 1 to 2 inches in diameter (especially where such guns are built into the camera itself).

Professional flash guns for large bulbs have reflectors from 7 or 8 to 16 inches in diameter.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

For compactness some flash guns use a folding fan type reflector which opens out to about 3 to 4 inches in diameter, but folds together into a space no larger than 1 × 1½ inches on the front of the gun.

The simplest reflector is a plain white or silvered disc held behind the bulb. Most flash holders, however, have curved reflectors which provide a more concentrated and even flood of light.

The most efficient reflector shape is the parabola which concentrates the light into a beam. This beam may be parallel, converging or diverging, according to whether the bulb is at the focus of the parabola, in front of the focal point, or behind it. Some reflectors of this type are adjustable to permit movement of the bulb to vary the angle covered. Many reflectors also provide for a vertical adjustment to centre bulbs of different sizes.

The reflector surface may be polished or satin finished. A polished reflector is the more efficient, but this type can give rise to extra brilliant "hot spots" or to areas of uneven illumination if the reflector shape is not formed with sufficient precision. A satin-finished reflector throws a little less light on to the subject, but diffuses it more evenly. This effect is still greater with matt white reflectors. Grained reflector surfaces are similar to the satin finish for diffusion, but are claimed to be more efficient.

Screens. Some flash guns are fitted with transparent or translucent plastic screens. These clip over the reflector or are screwed on and made to swing out of the way to allow the bulb to be inserted. The screens serve two purposes.

(1) The translucent type acts as a diffuser, softening the light from the flash and spreading it more evenly over the subject area. This involves a loss of light and therefore calls for more exposure.

CAPACITOR FLASH CIRCUIT. An anode battery charges the capacitor through a resistor and the flash bulb filament. On closing the shutter contact, the capacitor is short-circuited across the bulb and discharges, thus instantly firing it.

(2) Both translucent and transparent screens also act as safety shields to protect the subject against flying glass if a flash bulb should burst on firing. The reflector also protects the camera user.

One type of protective screen fits over the bulb itself when it is in the flash holder.

Means of Fixing. In practice it is often useful to have the camera and the flash gun firmly linked together to enable the two to be handled as one unit.

One way of doing this is to mount both the camera and the flash gun on a suitable bracket. The bracket may be fixed permanently to the battery case and attached to the tripod bush of the camera by a screw. The shape and size of the bracket are designed to suit the flash gun and camera in use.

Lightweight flash guns often carry a foot which fits into the accessory shoe of the camera for direct mounting. This method is not advisable for heavy guns, as the weight may distort the accessory shoe or the body of the camera.

Certain flash guns made for specific cameras are designed to fit into a suitable clip or screw on to the camera concerned.

Firing Plugs and Lead. Most flash guns incorporate a firing lead and plug to fit one or other of the various types of sockets on synchronized shutters. The lead may be permanently fixed to the flash gun, or it may carry a plug at the flash gun end to connect to an outlet on the battery case. Such an outlet is usually wired in parallel with the hand firing switch or button for open flash work.

Firing leads may be coaxial or twin cables. With a coaxial cable the outer lead is the earth connexion. The plugs, both for the shutter and for the battery case, are generally designed to fit only one way to prevent the insulated terminal of the battery case from being connected to the earth terminal on the shutter and so firing the bulb as soon as it is inserted in the lamp holder.

Originally manufacturers used various designs of flash socket on their shutters. With the exception of the first type listed below, which is nowadays the standard flash fitting, most of the others have become obsolete.

(1) Coaxial plug and socket of 3 mm. diameter. This is used on most Continental cameras, as well as on many British makes. The plug may be in line with or at right angles to the cable. Some cameras have a special catch which prevents the plug from being accidentally pulled out of the shutter.

(2) Coaxial plug and socket of 3·8 mm. diameter.

(3) A.S.A. bayonet plug and socket. These are used for some American cameras. The socket on the shutter resembles a tiny bayonet lamp cap, while the plug corresponds to the bayonet socket.

(4) A.S.A. twin pins and sockets (bipost). The shutter carries the pins, while a female plug

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

makes the connexion. These also are used for some American cameras.

(5) Non-standard types include various forms of two-pin and three-pin plugs, coaxial bayonet, etc.

With certain cameras the electrical connexion is fitted inside the clip which holds the flash gun to the camera, or inside the accessory shoe to which the gun is attached. In both cases the flash gun must be specially designed for the camera concerned, and no external firing lead is required.

Permissible Current. The various electrical connexions and contacts must withstand the maximum firing current likely to pass through them.

The better makes of flash cable and contacts are tested to an instantaneous voltage of the order of 600 volts and can thus carry the primary trigger surge of electronic flash units. The maximum steady current loading for periods not exceeding 1/10 second, is usually around 10 amps at 24 volts.

Test Lamps. Some of the more elaborate flash guns incorporate testing circuits with a built-in test lamp. This lamp enables the user to check the working of the synchro-contacts of the shutter, the connexions and firing lead, the battery, and the flash bulb itself. A separate test lamp (e.g., 6 volt motor-car bulb) inserted in the lamp holder in place of the flash bulb will also test all the above points except the flash bulb.

Extension Units. For multiple flash work it may be necessary to synchronize several flash bulbs to one synchronizer or shutter. The usual way of doing this is to use extension units which are linked to the main unit and shutter by means of extension cables. Several systems are possible for doing this:

(1) One battery or battery-capacitor unit fires several bulbs. The bulbs are connected in parallel or series (according to the circuit) and the extension units are plugged into a suitable extension socket on the master unit. The current must be strong enough to fire all bulbs simultaneously.

(2) One battery charges several capacitors each of which fires one bulb. The main unit is a normal capacitor flash gun, while the extension units are similar but with an extra connecting socket and no battery. The usual scheme is for the extension units to be connected directly to the shutter, and the main unit plugged into the extension unit. Alternatively the leads from each unit are plugged into a multi-way adapter which in turn plugs into the shutter. This is normally the most reliable system.

EXTENSION FLASH. One battery of a capacitor flash gun can power one or more extension units as well, each with its own capacitor. The units are here connected in parallel.

(3) Several separate capacitor flash guns, each with its own battery unit, are connected in parallel to the shutter or synchronizer. This again connects via a multi-way adapter to the various guns. The units are thus independent of each other as far as power is concerned. There is, however, the risk that the capacitor of one unit may fire the bulb of another when the latter is connected. It is advisable therefore to have a rectifier in the circuit of each gun to prevent its current from going into another circuit (e.g., if the resistance of the circuit of one of the other guns in smaller). Books: *Successful Flash Photography*, by L. A. Mannheim (London).

FLASH FOR INFRA-RED. Infra-red flash has been used for a variety of special purposes, including press photography in the blackout and in situations where a bright flash would be disturbing, candid photography, detection of criminals in the dark, cinema audience-reaction studies, unobtrusive instrument recording in aircraft, dark adaptation and other studies of the eye, and photography of industrial operations in the dark—e.g., sensitized material manufacture and processing.

Equipment. Infra-red flash photographs can be taken with ordinary cameras and flash attachments, the special requirements being a filter in front of the flash bulb to confine the rays to the infra-red, and a film sensitive to infra-red rays. In some cases it may be necessary to make a slight adjustment of the focus in the form of a slight forward shift as though the subject were somewhat nearer than its actual distance. Many modern lenses have an infra-red datum line marked on the focusing mount.

The light from ordinary flash bulbs and electronic flash tubes is rich in infra-red rays and both of these light sources are suitable for infra-red flash pictures.

CC-0. Jamia Hamdard. Digital Preservation Foundation, Gurugram

The filter fitted in front of the light source to confine the exposure to the infra-red is normally of a very deep ruby red which allows only a small amount of visible light to pass. Most manufacturers of sensitized materials for infra-red photography supply special filters or filter materials for use with their own infra-red plates and films. Normally the filter is so dense that the audience sees nothing of the flash, although anyone looking directly at the bulb will see a dim reddish glow at the instant of ignition.

Flash bulbs have been available which are coated with a lacquer which acts as an infra-red filter and lacquers are on the market by which the photographer can lacquer his own clear bulbs.

Plastic sheet bags have been made for slipping over the flash reflector or bulb, and having the characteristics of infra-red filters. It is a simple matter to fix a sheet of infra-red filter gelatin over the reflector, but it should be protected by sandwiching it between stout sheets of transparent plastic.

In arrangements where the flash is entirely independent of the camera, frames carrying the filters can be placed over the lights, or darkroom lamphouses can be used if an infra-red filter is inserted in place of the normal safelight glass and a sheet of tin or aluminium foil curved around the back of the bulb inside to increase the reflectance. Booths or other devices with infra-red filters covering them may also be constructed to house the lamps. In such cases the filters should be between sheets of glass since the heat of the flash might tend to destroy the brittle gelatin filters.

Technique. In infra-red flash photography, the subject should be unaware of being photographed, but it is practically impossible to make flash pictures in such a way that the subject could not in any circumstances see a flash. If there is enough illumination to give a reasonable exposure, anyone looking directly at the reflector when the flash is fired, will see a deep red flash. So the attention of the subject must always be drawn away from the light source, as in a theatre or cinema, where everyone is looking at the stage or screen, or the lighting must be indirect—e.g., "bounced" from the ceiling or a wall—or the exposure must be made through an existing and permanent red light, such as part of the illumination, or an exit sign. In direct infra-red flash photography, it is best to use a reflector which gives well-diffused rather than concentrated illumination.

The actual exposure depends on the nature and shape of the reflector and it is not possible to give precise data. But with the infra-red material and flash bulbs available through the normal sources of supply there is no difficulty in achieving a flash factor of 50 or even 100 for an exposure time of 1/50 second. The flash factor is the product of the *f*-number and the lamp-to-subject distance in feet. Detailed tables are given by the manufacturers.

Certain special films are available in 35 mm. form with greatly enhanced infra-red sensitivity which are particularly suited for infra-red flash photography. The guide number is as high as 200 with suitable flash bulbs, indicating a four times increase in infra-red speed.

Satisfactory audience-reaction photographs have been made in an auditorium 35 × 65 feet by placing five 1,000 joule electronic flash units in a booth at the side, pointing the reflectors to the ceiling, and covering them with sheets of infra-red filter between glass. Using indirect illumination of the audience and the earlier type of infra-red film, good exposures of about one hundred people in the middle of the room were obtained at *f* 3·5, the effective exposure time being 1/10,000 second.

For photographing a long row of operators spooling very fast aerial film in total darkness, twelve large flash bulbs were used, one suspended over each operator and machine, and two extra for supplementary illumination. All the flashes were fired together. Using the earlier infra-red film, a good picture was made at *f* 16 with open flash. W.C.

FLASHING. Method of varying the contrast of a photographic paper by using a brief auxiliary fogging exposure in addition to the printing exposure. First suggested by G. B. Harrison and J. Mitchell in 1950.

A paper suitable for projection printing is basically a high contrast bromide paper with a very sharp-toed characteristic curve and which, without a flash exposure, is suitable for printing very thin negatives. Introduction of an auxiliary exposure reduces contrast by lengthening the toe; the higher the proportion of flash to basic printing exposure the softer will be the result. The process is limited by the production of visible fog. The same principle may be adopted for control of contrast of contact papers.

It is immaterial whether the flashing exposure is applied prior to, simultaneously with, or subsequent to the printing exposure.

Altering gradation by the use of flashing techniques is simpler than using the so-called variable contrast papers which vary in contrast according to the wavelength of the light source to which they are exposed, and hence require a set of suitable coloured filters to exploit their possibilities to the fullest extent.

Although flashing papers will provide acceptable prints from a fairly wide range of negatives, the use of this method to deal with the very hard negative tends to give a print of rather veiled appearance; this is inherent in the method.

A typical flashing projection printer is provided with push-button controls for the auxiliary exposure, the appropriate button being selected according to the negative density range; the printing exposure is automatically controlled in the usual way by a photo-cell.

This technique of automatic printing is widely used in commercial photo-finishing establishments. H.P.

Flashing is also a standard technique in the making of photo-mechanical half-tone negatives where it is used to form a minute dense core in the centre of each dot, which helps to form a firm "shadow" (small dot) formation and is lost in the lighter tones which are represented by larger dots.

Local Flashing. The term "flashing" is also applied to a technique used to blacken parts of the print by exposing them to the direct action of white light. This is straightforward local fogging, and has no relevance to contrast control.

For example, certain types of photograph look more satisfactory when surrounded by a black border.

This is produced by flashing a narrow edging all around the exposed print. The centre of the print is shielded with a rectangle of black card, the negative is removed from the enlarger, and the light is switched on for a second or so in order to fog the border. The black card must be in good contact with the paper.

Selected areas of the exposed print may also be darkened by going over them with a small spot of light projected from a suitable pocket torch. The light should be just strong enough to produce blackening in about 5–10 seconds. Throughout the flashing process, the enlarger light is left switched on, with the orange filter in front of the lens, so that the image can be seen on the paper to guide the operation.

FLASH POWDER. Until the introduction of the flash bulb the only self-contained light source for indoor night photography was afforded by burning magnesium, either in the form of ribbon, foil, or more generally, powder. The first two are obsolete, as is the older form of magnesium powder. This was used in a special flash lamp burning methylated spirit, the powder being blown into the flame by air pressure from a bulb.

In its later form the magnesium powder is mixed with chemicals which make it easier to burn.

Powder of this type is used in a flash tray in which it is ignited by a spark generated by a wheel and flint. It can also be ignited by touch paper and an ordinary match, by plunging a lighted taper fixed to a stick into the heap of powder, or by an electrically-heated element.

Flash powder has largely been superseded by the modern flash bulb, and the electronic flash unit, but there are occasions when its use offers advantages—e.g., when the illumination is needed for a much larger area than that covered by the largest flash bulb. Greater illumination can be provided by a big quantity of powder spread in a trail instead of a heap. Used for this purpose, it is rather cheaper than the large-size flash bulbs.

Commercial flash powders are supplied in double containers. One holds the magnesium powder, the other the igniting compound. In the interests of safety these two powders must be kept apart in their containers until required for use.

After they are mixed, great care must be taken not to allow the powder to become damp or it may form lumps. These must be removed before using or there will be a risk of their jumping from the tray and causing damage or injury.

Flash powder must be carefully handled or it may produce severe burns and cause damage, and even start a fire. In some cases its use is prohibited.

Finally, it is not suitable to be used in connexion with the flash synchronized shutters.

Safety Precautions. Flash powder must be treated like an explosive. Never pour the powder directly from the container to the tray of the flash lamp. First place upon a sheet of paper, thence on the tray, and replace the lid or cork in the container immediately.

Should the powder fail to fire on the tray, pour it back on to the paper before investigating the cause. If the touch paper seems to have failed, do not approach or disturb it until it really has gone out. Keep the tray well away from curtains and furniture, and remove or cover anything valuable.

Ignition. The flash lamp is necessary to fire flash at a precise instant; otherwise a large tray of metal will do on which the required quantity of powder can be spread. The exposure is made by placing the touch paper supplied in the powder and touching it with a lighted taper on a stick.

When a large quantity of the powder is to be fired, it may be divided into a number of smaller flashes at different points. This is rather slow, but with interiors speed is not important.

Quantity. The quantity of powder necessary depends upon the distance from the subject, the tone of the walls, whether light or dark, the make of powder, and the speed of the film. As a rough guide to form the basis for further trials, using a fast panchromatic film, with the subject at 12 feet, and medium-light walls, 20 to 30 grains of the powder will be sufficient.

Flash Capsule. Flash powder also used to be

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

supplied in a capsule form which enabled it to be used as easily as a flash bulb. The capsule contained a measured quantity of smokeless flash powder formed around a wire filament connected to a pair of contacts which could be plugged into a cap for inserting in a flash holder in the same way as a bulb. When the firing battery was switched on, the wire heated up and fired the powder.

FLASH SYNCHRONIZATION

There are two basic methods of taking a photograph by flashlight: by firing the flash while the shutter is open, and by opening the shutter while the flash is alight.

Open Flash. The first method is the one practised with flash powder illumination; it is also used with flash bulbs, when it is called open flash exposure. With this method all the light of the flash is used in making the exposure, but, as the shutter has to remain open for a period that will include the whole time of ignition, it is not normally suitable for fast exposures. A charge of flash powder, for example, might take several seconds to burn, and the shutter would have to remain open for the whole of that time. A flash of this type can be used only with still subjects.

Flash bulbs have a much briefer period of ignition, so the shutter only needs to be open for a shorter time.

The open flash technique can still be adopted —i.e., the shutter is opened as for a brief time exposure, the flash is fired by hand, and the shutter is closed. It is possible in this way to leave the shutter open for as little as half a second. Even so, the method is only suitable for still subjects.

Synchronized Flash. The second and the modern way of taking flash photographs is to synchronize the firing of the flash with the shutter movement in such a way that the maximum brilliance of the flash coincides with the instant when the shutter of the camera is fully open at an instantaneous shutter speed. This synchronization of the flash with the shutter must allow both for the time the shutter takes to open and for the time the flash takes to reach its full brightness or peak. It can be achieved in several ways:

(1) By means of a flash firing contact built into the shutter.

(2) By means of a mechanical synchronizer coupled to the shutter.

(3) By means of an electro-magnetic shutte release connected to the flash circuit (magnetic synchronizer).

Synchronized Diaphragm Shutters. In a synchronized diaphragm shutter—i.e., all between-lens shutters and most behind-the-lens shutters other than focal plane types—a flash contact connected to a moving part of the mechanism closes the firing circuit of the flash at the right moment. This may be either when the shutter blades are fully or nearly fully open, or some time (usually about 1/60 second) before they begin to open. In the latter case a delayed action release mechanism may be incorporated to delay the shutter opening for a time corresponding to the firing delay of the bulb. There are thus several kinds of synchronization:

(1) X-synchronization fires the flash at the instant the shutter blades are fully open. The flash contact is generally a simple make-and-break contact connected to the ring or lever actuating the blades. X-synchronization is suitable for electronic flash which has no firing delay, i.e., where the flash reaches its peak almost the instant the firing circuit closes. Any shutter speed up to the fastest (1/300 or 1/500 second) can be used.

Class M, and S flash bulbs can also be synchronized with an X-synchronized shutter, provided the shutter speed is slow enough to cover the firing delay of these flash bulbs, as well as an appreciable part of the half-peak duration. That is usually a shutter speed of 1/25 to 1/30 second.

(2) F-synchronization closes the firing circuit

SYNCHRONIZATION. Top: A class M bulb (dotted curve) can be synchronized with an X type shutter at 1/25 second to catch all the light. At 1/100 second the shutter closes too early, but with M synchronization any speed captures the peak of the flash. Bottom: With electronic flash (dotted curve) only X-synchronization is possible; when set to M the shutter only begins to open after the flash is finished.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

when the shutter blades are half open, i.e., about seven to eight milliseconds (1/125 to 1/150 second) before they are fully open. The flash contact is of the same type as that of X-synchronized shutters. F-synchronization used to be intended for the now obsolete Class F flash bulbs as the peak brilliance of the bulb coincided with the full opening of the shutter. Class M and S bulbs can still only be synchronized at slow shutter speeds. F-synchronization can also be used with the obsolete relay-fired electronic flash units which have a firing delay of about eight milliseconds due to the operation of the relay switch, but normal (Class X) electronic flash cannot usually be synchronized.

This type of synchronization was at one time provided on diaphragm shutters and is still built into some of the cheaper shutters, as found on box cameras, where the shutter takes fairly long to open (irrespective of the time it stays open).

Both X and F-synchronization are based on the fact that the exposure time is longer than the flash duration. The shutter speed therefore plays no part in exposure determination unless the flash is mixed with other light such as daylight.

(3) M-synchronization closes the firing circuit about sixteen to eighteen milliseconds (roughly 1/60 second) before the shutter is fully open—well before the blades start to move. The flash contact is closed by the release mechanism, but an escapement (generally shared with the mechanism of the self-timer) delays the opening of the blades for the required time.

This synchronization is suitable for class M flash bulbs (which have a half-peak delay of 16 milliseconds) used at all shutter speeds up to the fastest (1/300 to 1/500 second). Class S bulbs still need slow shutter speeds, while M-synchronization is not suitable at all for electronic flash.

With M-synchronization the exposure time is shorter than the flash duration, which is why the shutter opening must be timed so that the blades open and close while the flash is at its peak. The faster the shutter speed, the less of the light is utilized, and exposure determination (e.g., by guide numbers) must therefore take the speed into account.

M-synchronized shutters usually also incorporate X synchronization. They are often referred to as speed-synchronized or (incorrectly) as fully synchronized.

(4) XM-synchronized shutters have two flash contacts built in, one for X and one for M-synchronization. A synchronizing lever selects the type of synchronization required, or the shutter may have two separate flash outlets. Many precision shutters are of this kind and are thus equipped to tackle a wide variety of flash subjects.

(5) MF and XMF-synchronized shutters incorporate the different types of synchronization indicated by the respective letters. They are similar to XM-synchronized shutters, but rare nowadays as class F bulbs are no longer made.

(6) Full synchronization denotes that the delay of the synchronizing mechanism is continuously adjustable instead of being limited to two (or three) fixed settings. The term is also used incorrectly for XM-synchronized shutters.

The adjustment of fully synchronized shutters may range from 0 to 25 or even 30 milliseconds, thus covering even Class S flash bulbs. In practice full synchronization is of no special advantage any longer, since virtually all flash bulbs have standardized firing delays according to their class.

SHUTTER SPEEDS AND SYNCHRONIZATION

Flash Class	*Setting on Diaphragm Shutters*		*Focal Plane Shutters*	
	X	*M*	*Simult. Release*	*Delayed Release*
X	1/500*	—	1/60†	—
F	1/100	—	1/30‡	—
M (small)	1/30	1/500*	1/30‡	—
M (large)	1/30	1/500*	1/30‡	1/60†
S	1/15	1/30	1/10	1/125
FP	1/30	1/500*	1/30‡	1/1000*

The speeds are the top speeds that can be synchronized with the given settings and flash bulbs. Older cameras may have settings of 1/25, 1/50, etc. second instead of 1/30, 1/60, etc.
*or fastest speed of shutter.
†1/30 second on larger cameras.
‡1/15 second on larger cameras.

Synchronized Focal Plane Shutters. In a focal plane shutter the synchronizing contact may be closed by a cam on the blind roller.

The problem of focal plane shutter synchronization is somewhat different from that of diaphragm shutter synchronization because the shutter exposes the negative in successive strips instead of all at once. For synchronization at high shutter speeds the peak of the flash must coincide with the moment when the blind begins to uncover the film, and last long enough to cover the full time it takes the blind to travel across the focal plane. This time is usually 20–50 milliseconds irrespective of the shutter speed set. The focal plane shutters of miniature cameras take the shorter time quoted; shutters of larger cameras—e.g., press cameras—take longer.

For that reason special long-flash bulbs (Class FP) are used for focal plane shutter synchronization. Bulbs of this type have a half-peak duration of 20 milliseconds or more, and the peak itself is comparatively flat, yielding an even level of light throughout the flash.

Class M and S bulbs, even with their long half-peak duration, are less suitable for this purpose as the flash changes appreciably in intensity above the half peak, and the negative

FOCAL PLANE SYNCHRONIZATION. Top: *An ordinary flash bulb must be fired just before the shutter is open so that the full opening coincides with the peak.* Bottom: *An electronic flash is fired only when the shutter is fully open. In both cases a slow shutter speed must be used which simultaneously uncovers the whole frame; long peak bulbs permit fast speeds as the flash lasts while the shutter runs down.*

is not exposed evenly. Generally one or both ends, corresponding to the beginning and end of the travel of the blind, are under-exposed as compared with the centre.

All types of flash other than FP bulbs are therefore best synchronized with a shutter speed at which the blinds are momentarily open to the full size of the negative. This is generally 1/50 second with miniature cameras, and 1/20 or 1/25 second with larger types. At higher speeds than this, the blinds close up to form a slit which travels across the negative and exposes it piecemeal.

Some focal plane shutters incorporate two contacts wired in series, both of which must be closed before the flash can be fired. One contact is the normal synchronizing contact, while the other is connected to the release button. This prevents the firing circuit from firing any bulbs in the flash gun while the shutter is being tensioned. This release contact is additional to any further synchronizing contacts that may be built in, and works in series with any of them.

As with diaphragm shutters, there are several kinds of synchronization for focal plane shutters.

(1) Simultaneous release fires the flash when the first blind has reached the end of its travel. It corresponds to X-synchronization on diaphragm shutters. Provided the set speed is 1/60 second (often marked by a special symbol), or 1/15 to 1/30 second, or slower, with larger cameras, the negative is fully uncovered at this instant. This kind of synchronization is thus suitable for electronic flash at these speeds, or for most types of flash bulbs (all classes) at the next slower speed (1/30 or 1/15 second). The slower speed is required with bulbs to allow for the firing delay.

(2) Delayed release closes the firing circuit about sixteen to twenty milliseconds before the first blind begins to uncover the film. This corresponds to M-synchronization with between-lens shutters, but is suitable only for class FP bulbs with which any shutter speed can be used. Class M bulbs, even at slow speeds, cannot be synchronized satisfactorily since the flash is over before the first blind has finished travelling. Some class S bulbs can be synchronized under these conditions, but again the exposure may be uneven over the negative, especially with larger cameras.

On certain cameras the delayed release closes the firing circuit 18 milliseconds before the first blind has reached the end of its travel. This limits the use of FP bulbs to slow shutter speeds, but permits synchronization of class M bulbs at intermediate speeds (up to about 1/100 second on miniature cameras).

Electronic flash (class X) cannot be synchronized with a delayed release contact.

(3) Multiple synchronized focal plane shutters incorporate both simultaneous and delayed release contacts, analogous to an XM-synchronized diaphragm shutter. Generally, however, no synchronizing lever is provided, and the two contacts are wired to separate outlet sockets. Sometimes the shutter speed dial is coupled with the synchronization so that it brings in the simultaneous contact at speeds of 1/50 second and slower, and the delayed release contact at faster speeds.

(4) Fully synchronized focal plane shutters have a dial or similar device for setting the firing delay. The figures on the dial do not necessarily denote delay times.

Wiring of the Shutter. The flash contacts inside the shutter are wired through to a suitable flash socket on the shutter housing or on the camera body. In most cases one side of the circuit is earthed to the metal parts of the shutter, while the other is insulated from it. It is therefore important to preserve the correct polarity when connecting the flash plug to the shutter. This is generally achieved by the use of the now standard co-axial flash socket; the outer contact is earthed, and the inner contact is insulated.

With a symmetrical two-pin socket both contacts must be insulated. Alternatively, the two pins may be different in size or arranged so that the plug can only be inserted one way round, preventing a short circuit which would prematurely fire the flash. Unsymmetrical three-pin sockets serve the same purpose, the third pin acting as a locating device.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

MECHANICAL SYNCHRONIZER. A contact inside the plunger unit closes the firing circuit as the shutter opens.

Mechanical Synchronizers. Older shutters without flash contacts can be synchronized by means of an external synchronizer. The simplest form is the mechanical synchronizer which makes the contact inside an attachment which screws into the cable release socket or is linked with the release button of the camera.

The firing circuit is closed during the movement of the plunger or button of the attachment as it releases the shutter. A simple adjustment moves the point of contact to adapt the synchronizer to different shutters.

Most mechanical synchronizers are of the simultaneous release type, corresponding to X or F-synchronization. Delayed release is difficult to time reliably.

Magnetic Synchronizers. These release the shutter by the action of a solenoid which operates the release lever. The energizing current for the solenoid also fires the flash.

The solenoid is a coil of insulated wire surrounding a soft iron core. When a current passes through the wire, the coil becomes a powerful magnet which can be made to attract a suitable iron armature connected to the shutter release. Passing a current through the solenoid therefore operates the release and trips the shutter.

The solenoid itself simply operates an electrically controlled remote shutter release. To turn it into a magnetic synchronizer, a flash circuit is wired in parallel with it, and powered from the same battery. Closing the circuit therefore fires the flash as well as releasing the shutter.

MAGNETIC SYNCHRONIZER. The firing current for the flash actuates the armature of the magnet and thus trips the shutter. A set screw adjusts the timing and controls synchronization.

Magnetic synchronizers are always delayed release synchronizers, since the firing circuit must close before the shutter can be released. The delay depends on the distance the armature has to travel before it trips the shutter, and is usually adjustable.

Magnetic synchronizers need a fairly strong current for their operation, and the batteries used must be capable of giving at least three amperes.

Since the solenoid depends on a steady flow of current, it is not normally suitable for operation from a battery-capacitor unit, which only supplies a current pulse.

Testing Synchronization. Testing methods fall into two groups: visual and photographic.

Visual methods depend on observing the flash or a suitable test lamp through the shutter —or next to it—during release.

The simplest method works well with X-synchronized diaphragm shutters using an electronic flash unit. Direct the flash at a light wall and point the camera at the same wall. Open the camera back and release the shutter (with electronic flash connected to the synchronizing outlet).

If the synchronization is correct, the shutter appears fully open when the flash fires, a full size bright circle being visible through the camera back.

Incorrect synchronization will show the silhouette of the partly open shutter blades against the bright circle—or no bright circle at all. The lens aperture should, of course, be wide open.

The same system works with focal plane shutters, but here incorrect synchronization results in only part of the negative area appearing illuminated.

Photographic methods involve directly or indirectly photographing the flash. With diaphragm shutters, a direct photograph of the flash bulb, taken at a small aperture and synchronized with the shutter, will show the filament or charge in the process of combustion. The exact stage of this combustion in the picture will indicate whether the flash is early or late in firing.

With focal plane shutters, a picture of the flash itself is not so useful, as it is at a different stage in different parts of the negative. A better arrangement is to photograph a white area illuminated by the flash, so that it fills the negative.

If the exposed area appears uniformly lit, the synchronization is in order. If one or the other end of the negative appears lighter than the other, synchronization is incorrect. The extent and position of the lighter area, relative to the movement of the shutter, then indicates whether the flash is early or late, and by approximately how much.

A falling off in density at both ends of the negative indicates that the flash was too short for the shutter speed employed.

Professional testing methods involve the use of oscillograph equipment, and record the closing of the flash contact and the shutter opening as traces on the screen of a cathode ray tube. This is the quickest and surest way of testing synchronization, but is outside the scope of the amateur photographer. L.A.M.

FLASH TECHNIQUE

Modern flash equipment has greatly increased the scope of photography under almost all conditions. The flash bulb and the electronic flash unit will not only get pictures in the dark; they can be used in conjunction with numerous other light sources, particularly with daylight. Thus in weak light flash enables instantaneous exposures to be used at small lens apertures, thus giving greater depth of field than would otherwise be possible. Flash can also be used to simulate sunlight on a dull day. In strong sunlight flash can be used to lighten the shadow areas of the subject and so even up excessive contrasts such as are beyond the range of colour film.

Flash can be used to stop fast movement, and moving subjects can be brought within the scope of slower films, particularly colour emulsions. The fastest movement can be completely arrested by electronic flash.

Subjects which are disturbed or harmed by the heat and glare of conventional artificial lighting, as may happen in portraiture and when photographing flowers and insects, can safely be photographed with flash.

GUIDE NUMBERS. The flash distance and f-number for correct exposure are inversely proportional, and for any one film and flash bulb their product is constant. This product is the guide number and serves for quick exposure calculation. Correct aperture is guide number divided by distance. (Guide number is here 110, so at 10 feet aperture should be f 11.)

Guide Numbers. Exposure with flash is usually determined by means of the guide numbers quoted by flash bulb and electronic flash unit manufacturers. These numbers are so computed as to take account of the power of the flash and the speed of the film, and are the product of the lens aperture (*f* value) and the lamp-to-subject distance in feet. To find the correct lens aperture it is therefore only necessary to divide the guide number of the bulb in use by the known lamp-to-subject distance. Conversely, the correct lamp-to-subject distance for a given lens aperture can be ascertained by dividing the guide number by the known aperture.

The guide number system takes into account the fact that the amount of light reaching the subject varies inversely as the square of the distance from the light source. When altering the flash-to-subject distance it is therefore important to remember that, if this distance is doubled, only one quarter of the light reaches the camera; and if it is halved, the amount of light is increased four times. In the former case, the lens aperture will have to be opened up two whole stops, and in the latter, it must be stopped down by the same amount.

The normal guide numbers apply only in cases where the camera shutter remains open throughout the duration of the flash, which with flash bulbs varies between 1/25 and 1/200 second. If the shutter only remains open during part of the flash, less light is able to affect the film during the exposure, and allowance for this must be made by reduction of the guide number. The duration of electronic flash is so brief (1/800 to 1/2,000 second) that, provided the shutter is of the between-lens type and is accurately synchronized, the normal guide number can be used.

Guide numbers are only intended as a guide to the correct aperture and flash-to-subject distance under average conditions. It is assumed that the flash bulb or electronic tube is used in an efficient reflector, that the subject is of average tone value and located in a medium sized room with light-toned walls. If any one of these assumptions does not apply, it may be necessary to open or close the lens aperture by one whole stop or more. With colour film (and

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

particularly with reversal emulsions), which has much less exposure latitude, it is advisable to aim at correct exposure to within half a stop either way.

Camera Guide Number Scales. Some cameras carry an additional scale, used in conjunction with the distance or aperture scale, to indicate correct flash exposures.

There are two systems. The first is a simple scale of guide numbers, mounted on the aperture ring or on a ring next to the aperture scale. On setting the guide number to be used against the distance (either on the focusing ring or on a secondary distance scale), an index shows the corresponding required lens aperture. Alternatively, the index may have to be set against the distance and the aperture read off for each guide number.

The second type found on certain cameras goes one step further to make the procedure semi-automatic. Here the act of setting the guide number on the scale couples the aperture control with the focusing movement. Focusing on a closer distance automatically closes down the lens aperture, focusing on more distant subjects opens up the aperture. In this case the focusing movement is also restricted to a certain range which corresponds to the distances over which the aperture range of the camera can yield correct exposures with the selected guide number. Thus with a guide number of 220 and a smallest stop of *f*/22, 10 feet is the nearest distance at which a correct exposure is possible. So when set for this method of operation with a guide number of 220, the camera will not focus down below 10 feet.

Adjusting Exposure. If use of the normal guide numbers results in consistently wrongly exposed results, the numbers can be converted according to the following table, which provides adjustment of exposure between two times and one half of that resulting from direct calculation.

When a second flash as a fill-in light is placed appreciably farther away from the subject than the key light, the guide number of the latter can remain unchanged for purposes of calculating the exposure. But if two flash bulbs are used in the same position, the guide number should be multiplied by 1·4. When three lamps of the same type are used, multiply the guide number by 1·7, and with four, multiply by 2.

ADJUSTMENT OF EXPOSURE

Change of lens aperture:	*Multiply Guide Number by:*
1 stop larger	·70
½ stop larger	·84
1 stop smaller	1·4
½ stop smaller	1·2

As a general rule, where two flashes of different strength are used at different distances, the exposure can be worked out as follows. Find the aperture required separately for each flash from the guide number and the distance. If the resulting apertures are the same, use one lens stop smaller. If the apertures differ by ½ to 1½ lens stops, use half a stop smaller than the smaller aperture (higher *f*-number). If the difference is more than two lens stops, use the smaller stop for the exposure and ignore the larger one.

With three flashes combine the exposure for the two more powerful ones in the way just described, and compare the resulting stop with the lens stop for the third flash. Then combine again in the same way. With four or more flashes proceed similarly; usually the effect of these additional flashes—if weaker than the first three flashes—can be ignored.

As it is impossible to judge lighting effects with flash in advance, Photoflood lamps can sometimes be used to advantage for this purpose. If an exposure meter reading is taken of the experimental set-up, it is then possible by trial and error to work out the relative power of the two forms of lighting and so calculate the flash exposure by this means. It is advisable to keep a record of each lighting set-up including the exact position of the lamps and their distance from the subject. This makes it easy to reproduce the same conditions at will and so ensure correct exposure, which is particularly critical with colour film.

There are special exposure meters that can read flash exposures. With electronic flash, taking a reading involves setting up all the flash units and firing them in synchronism while taking an exposure reading. With flash bulbs this is however expensive, since it means wasting one set of bulbs for the exposure reading, and then using a further set for the actual exposure.

Flash at Camera. The simplest and handiest position for a single flash gun is at the camera, to which it can be secured by a bracket. This is an excellent position when flash is used as auxiliary lighting to soften shadows in daylight, but has certain disadvantages when flash is the sole light source. Results are somewhat

FLASH ON THE CAMERA. The easiest way of taking flash shots, as both camera and flash holder are firmly connected and freely mobile. However, it yields flat lighting and a heavy shadow close behind the subject.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

USING A FILL-IN REFLECTOR. A white reflecting screen on the shadow side of the subject will lighten and soften the hard shadow cast by a single flash bulb.

BOUNCE FLASH. The flash is directed at the ceiling and walls so that the subject is lit by soft diffused light, without harsh shadows. The exposure must allow for lower light.

flat and lacking in modelling, a sharp black shadow is cast behind the subject, whose eyes appear with unnaturally light pupils, due to an internal reflection in the retina. With colour film the same reflection causes the eyes to appear red.

Modelling can be improved by placing a reflecting screen to one side of the subject, using for example a white card or sheet or a board covered with silver paper, placed in such a position that the flash is reflected on to the shadow side of the subject.

Flash Remote from Camera. The drawbacks mentioned above are eliminated if the flash can be placed slightly above and to one side of the camera.

If the flash lead is not long enough for the purpose, it may be possible to use the open flash technique, securing the camera to a tripod, setting the shutter to B or T, and firing the flash separately while the shutter is open; but this is only feasible when the subject is relatively static. Alternatively a solenoid at the flash gun can be used as a remote control shutter release, the camera being held in one hand, the flash gun in the other.

Indirect Flash. When the subject is in more than one plane, lighting can be equalized to a certain extent by pointing the reflector slightly upwards so that the centre of the beam strikes the ceiling and is reflected down again while only the edge of the beam strikes the foreground of the subject directly. This method calls for a lens aperture two stops larger than normal. If there is a considerable distance between foreground and background, the reflector should be turned right away from the former and directed straight towards the latter. The lens aperture in this case should be calculated for the background.

Flash can also be directed away from the subject altogether and aimed at light walls and ceiling, so as to bounce back to the subject—hence the term bounce flash. This method gives an agreeably diffused result, but with colour film it can obviously only be used when the walls and ceiling are dead white. The lens aperture must be two to three stops larger than when direct flash is used.

Flash Without Reflector. Very natural lighting effects can be obtained in interiors by dispensing altogether with the reflector. In small light-coloured rooms the lens aperture required will be one stop larger than normal; bigger rooms call for one and a half stops more, and dark-toned rooms two and a half stops. Never use flash bulbs at the camera without reflector; serious injury may result in the event of a bulb bursting.

In general, when working with only one flash bulb, make as much use as possible of the reflecting power of walls to lighten shadows.

FLASH OFF THE CAMERA. The flash is connected by an extension cable and held above and to one side of the camera. Yields better modelling and separates the shadow.

TWO FLASHES. If an extension unit is available, it can be used as a fill-in light on the shadow side of the subject.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Take care that the image of the bulb itself is not reflected back to the lens by mirrors, windows or other reflecting surfaces.

Two Flashes. The quality of results is greatly improved if more than one flash unit is available. Though the outfit becomes more cumbersome a second flash-gun is a real advantage, even in action and press photography. It is often possible to persuade a bystander to hold the second gun; or it can be fixed in position with a universal clamp.

With a single flash gun the range of contrast between highlight and shadow areas of the subject may well be beyond the range of the paper on which the negative is printed. With a second flash, we immediately have full control of contrast. The normal procedure when using two flash bulbs of equal power is to have one flash gun remote from the camera but nearer the subject as main light, and the second flash-gun at the camera as a fill-in. In this way the fill-in flash softens the shadows cast by the main light without casting any of its own. Alternatively the relative power of the flashes can be adjusted by using different types of bulb for main light and fill-in.

Placing Fill-in Flash. Contrast adjustment will normally be effected by moving the main flash relative to the subject, while the camera with its fill-in flash remains stationary. As the light reaching the subject varies as the square of the distance between it and the flash bulb, a convenient way of memorizing the appropriate flash-to-subject distances for given contrast ratios is to refer to the *f*-numbers engraved on the camera lens diaphragm. According to the calibration, these will either read 4, 5·6, 8, 11, 16 and 22, or 3·5, 4·5, 6·3, 9, 12·5 and 18. As is well known, each number represents an aperture admitting half the amount of light of its left-hand and double that of its right-hand neighbour. If an illumination ratio of 2 to 1 is required and the camera and fill-in flash are placed at 11 feet from the subject, the main flash gun should be placed at 8 feet. If a ratio of 3 to 1 is desired, respective distances should be 11 and 6·3 feet; and for a ratio of 4 to 1, 11 and 5·6 feet.

Three or More Flashes. When using more than two flashes, the best method of adjusting the lighting is to replace the flash bulbs temporarily by Photofloods in appropriate light sockets and reflectors and judge the effect visually, calculating the exposure by the method already described.

Though it might appear less complicated to dispense with flash altogether and make the exposure by Photoflood light, actually flash offers very definite advantages which outweigh the extra trouble involved. First and foremost, the much higher light output of flash bulbs makes it possible to use smaller apertures and thus obtain greater depth of field. Then the ability to synchronize the flash to the instantaneous shutter speeds makes it unnecessary

MULTIPLE FLASH. One flash holder can illuminate a large room if the camera is set up on a tripod, the shutter opened for a time exposure, and the flashes fired in succession from various points. Avoid directing any flash into the lens.

for models to remain motionless, which is an obvious advantage when children or animals are involved, and results in much more natural and relaxed poses. For colour portraiture, with the comparatively slow films at present available, flash is almost indispensable to those who do not have access to an elaborately equipped professional studio.

Multiple Successive Flashes. The ability to fire successive flashes with electronic units can be turned to good account with static subjects such as interiors, architecture, and copying.

The flash tube can be recharged and fired from different positions to provide modelling and soften or entirely eliminate shadows. Unless flash is the sole light source it is necessary to close the camera shutter during the recharging period. Flash bulbs can also be fired in succession, but if a large number are required, the cost becomes prohibitive.

Flash and the Background. In the simplest case of a single flash on the camera, the subject casts a shadow on the background. The shadow is just visible from the camera position as a black border around the half of the subject on the opposite side of the camera to the flash—or below it where the flash is mounted immediately above the lens. The closer the subject is placed to the background, the more obvious this fringe of shadow becomes. This is because the background receives almost as much light as

EXTENSION FLASH WITH REFLECTING SCREEN. With a reflecting screen used to fill in harsh shadows, the extension flash can be used as an effect light on the background.

the subject. As the background is pushed farther and farther back it becomes darker in tone and the shadow becomes less obvious.

So with a single flash source on the camera, there is a choice between a light-toned background with a heavy subject shadow, or a dark-toned background with little or no shadow.

Where the background is to be shown as light in tone as the subject—and this is the case with most interiors—it is generally sufficient to direct the flash on to the ceiling or an adjacent light-toned wall—i.e., to use "bounce" flash technique. The flash is then fairly evenly distributed over the subject and the background (so long as they are only a few feet apart) and no hard shadows will appear anywhere. The drawback here is that the lighting is often too soft; it lacks depth and relief and gives no control of the relative tones of subject and background. It is satisfactory, however, for subjects of general interest where the subject is no more important than its surroundings.

For greater control it is necessary to use a separate flash—or Photoflood lighting—on the background. Illuminated in this way, the background can be made to reproduce as light in tone as wished by bringing the background light closer. The background illumination may be directed from immediately behind the subject and concentrated on the area where the shadow will fall from the principal light mounted on the camera. Or the principal light may be moved up and to the side so that it no longer casts a shadow on the background. (In this case a fill-in flash or white surfaced reflector will have to be used to light up the shadow side of the subject.)

Out of doors, supplementary flash lighting may be used for the reverse effect—i.e., to brighten the tone of the subject in relation to its background. This technique is often useful when the subject is dark in tone and is seen against a sunlit background. The normal camera exposure is adjusted so that the background will be under-exposed and come out fairly dark in a straight print. The flash distance is then calculated to give a correctly exposed subject at the aperture and shutter speed selected for the daylight exposure.

In colour work it is not possible to darken the tones of the sky by adding a colour filter as in black-and-white photography. The filter would simply tint all the colours of the subject and falsify all the values. Under certain conditions a polarizing filter can be used to darken some of the sky, but it does not give complete control. Flash, used in the manner described above, however, will light the subject normally at an aperture and shutter setting that will leave the sky under-exposed and dark in tone. And although the sky will be darker than in a normal exposure made without flash, its colour and the colours of the rest of the subject will remain reasonably the same. With flash bulbs it will be necessary to use a suitable blue filter over the lamp or a special blue-dipped daylight bulb to correct the colour temperature. No filter is required with electronic flash since this has approximately the same colour temperature as daylight.

CC-0. Agamnig Digital Preservation Foundation, Chandigarh

For colour shots with flash, colour films designed for short exposures must be used rather than the special types produced for long exposure times in the studio. The use of the long type of colour film—even with correction filters—may lead to loss of speed and changes in colour rendering, owing to reciprocity-failure effects.

Flash and Daylight. Flash can be used as an auxiliary light source to soften hard shadows resulting from exposures in bright sunlight. This is particularly useful with colour film, which can only record a limited contrast range. The technique is often known as synchro-sunlight.

When calculating the correct balance between daylight and fill-in flash it should be remembered that with flash bulbs, the slower instantaneous shutter speeds (e.g., 1/25 second) when the flash duration is shorter than the shutter opening, have no effect on the power of the flash. The full flash intensity is only reduced when the shutter speed is faster than the flash. When this takes place depends on the flash duration, which varies according to the type of bulb from 1/25 to 1/200 second. The duration of electronic flash discharge is always shorter than the fastest shutter speed with which it can be synchronized.

Generally therefore the shutter speed only influences the amount of daylight reaching the film, and not the flash intensity. Thus an exposure of 1/50 second will admit only half the daylight admitted by a 1/25 second exposure, without reducing the flash intensity.

Balancing Daylight and Flash. The desired balance between daylight and fill-in flash can therefore be obtained by varying either the shutter speed (affecting the daylight), or the flash-to-subject distance (affecting the flash intensity.

SYNCHRO-SUNLIGHT. A synchronized flash can serve as fill-in light in outdoor shots against the sun. The exposure must be carefully balanced not to overlight the shadows.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The flash intensity can also be altered by using a bulb of different power or by placing a piece of cloth over the bulb. (With colour film, such cloth must be dead white so that it does not affect colours.)

The normal procedure in practice is to set shutter speed and lens aperture as for an exposure to daylight only. Next divide the guide number of the flash bulb to be used by the lens aperture already selected. The resulting figure gives the flash-to-subject distance at which daylight and flash will illuminate the subject with equal intensity. If a relative intensity of 4 to 1 between daylight and flash is desired, the flash-to-subject distance must be doubled.

Simulating Sunlight. To simulate sunlight in dull weather, or to use flash as an effect light, reduce the flash-to-subject distance by half again, so that you are exposing according to the guide number. The flash then becomes the main light.

When using colour film, balanced for daylight, the flash bulb must be blue-tinted so that it will match the colour temperature of daylight.

Electronic flash, being of approximately the same colour temperature as daylight, is quite suitable for the purpose without modification.

FLAT FILM. Type of sensitized film material, also known as cut or sheet film. It is available in normal plate sizes and, to minimize buckling, usually has a thicker base than roll film.

See also: *Films.*

FLATNESS. Term applied to photographic prints exhibiting no clear black or white tones; lack of contrast.

FLATTENING PRINTS. Prints on drying tend to curl towards the emulsion surface. They can be flattened by various methods—e.g., pressure or stretching over the edge of a board in the reverse direction of the curl.

See also: *Drying.*

FLEXICHROME PROCESS. Obsolete commercial process for producing coloured prints from black-and-white negatives. The negative is printed on a special stripping material. This is developed in a tanning developer which hardens the gelatin in the image areas. The unhardened gelatin is then washed off in hot water leaving a swollen relief image.

A bleacher is applied to remove the silver image and the material is soaked in a grey dye which is absorbed by the gelatin matrix in proportion to the thickness of the gelatin and thus in proportion to the original silver deposit. The gelatin layer is then stripped and transferred to a paper support.

Special coloured dyes are next applied to the grey image. These dyes displace the grey dye and leave a colour image which varies in depth of tint according to the amount of gelatin available. In the same way, a second colour may be applied to displace the first.

The process allows the photographer to exercise almost unlimited control over the final result. At the same time, the colours will "take" only in proportion to the thickness of the gelatin image, so that the process remains photographic.

Flexichrome used to be popular for producing colour originals for magazine illustration from ordinary negatives, and was also practised by some portrait photographers and pictorial workers for exhibition.

See also: *Colouring prints.*

FLOODLIGHT. Source of main general lighting. A floodlight may consist of one or more quartz iodine or 500-watt tungsten filament lamps mounted in a white enamelled reflector shaped like a shallow box or trough. The light from such a unit spreads evenly over the subject and does not cast hard shadows.

Floodlights may hang from the ceiling, stand on the floor, or be mounted on an adjustable stand on wheels. In portrait studios the floodlights are generally part of the permanent fittings. For amateur use, a Photoflood in a shallow matt-surfaced reflector makes a useful floodlight.

See also: *Lighting equipment.*

FLOWERS. Photographs of flowers are almost always better when they are taken against a plain background, and for tall flowers like hollyhocks, sunflowers, etc., the best background of all is the blue sky. Sunshine is not essential but it helps to add modelling and texture.

Most flowers require a 2× or 3× yellow or green filter and panchromatic film. The shutter speed must be kept short enough to deal with movement of the subject in the wind.

If the natural background is fussy, the subject should be photographed against a large piece of card, light or dark grey to suit, supported behind the plant or fastened on to it by paper clips. With short-stemmed plants the background card may be pinned between wooden stakes pushed into the ground. The card may be curved behind the chosen flower to protect it from the wind.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The colour of the background should be chosen to contrast with the subject, a light flower being given a darker background and vice versa. It is generally better to take a few flowers well grouped than a large mass of blooms of the same sort. The whole group, including the foremost petals, must be sharply focused.

Backlighting emphasizes the delicacy and transparency of flower petals and foliage, and sidelighting shows up the texture. Over-dark shadow areas should be lightened by holding or supporting a piece of white card or cloth so that it reflects the principal light into the dark parts.

Flowers Indoors. When cut flowers are photographed indoors, much of the appeal depends on careful arrangement and choice of setting. The container should be in keeping with the type of flower; dainty flowers need delicate, fragile containers; large, sturdy blooms look best in a substantial jug or vase. And as the flowers are the important thing, the container should be plain and unobtrusive. For the same reason furniture and other ornaments should be kept out of the picture.

Grouping flowers attractively calls for some skill and flair; it is generally better to avoid symmetrical arrangements and the blooms should not be bunched in the dead centre of the picture or spread out at regular intervals.

Small Flowers. Very small flowers call for true close-up technique. They can be held in position with Plasticine and photographed by artificial lighting but the work must proceed quickly because the flowers wilt when they are out of water and under the warm lighting. Alternatively a sheet of heat-resisting glass can be placed in front of each lamp to minimize the heating effect. The grouping of such small subjects must be kept as nearly in one plane as possible because of the extremely shallow depth of field of the lens at such close distances.

Lighting indoors should be made to look as natural as possible—i.e., it should fall from above and to one side. Often the best lighting arrangement comes from standing the flowers on a window ledge—but not in direct sunshine—and brightening up the shadow side with a reflector.

Equipment. The best camera for flower photography is either a plate camera with back focusing, or a single lens reflex. Both of these cameras have focusing screens on which the picture can be comfortably studied, and can be fitted with long focus lenses which give big pictures without the distortion of a too-close viewpoint. Miniature cameras—particularly those with special close-up magnifying reflex attachments—can also be used. Finally, almost any camera with a supplementary lens of about 1–2 diopters can be made to turn out good flower photographs within its own limitations.

Sensitized Material. There is no room for artistic falsification of tone values in flower photography. All the colours of the subject must be reproduced in their true brilliance or the photograph will look false to anyone who knows anything about flowers. So the subject demands a medium speed panchromatic film with perhaps a 2× green filter.

This means that deep red, blue, or mauve flowers and their foliage will all reproduce in more or less identical shades of grey. The result is that such flowers are lost amongst the foliage. It is of course possible to lighten the colours of the flowers with a suitable filter, but only by falsifying the tone values. If the photographer simply wants to make flower pictures, he should avoid flowers of such deep shades and use lighter coloured varieties.

Colour film is the only material that will do justice to flowers, and there are few better subjects for turning into transparencies. Here, as elsewhere, the photographer must resist the temptation to cram as many highly coloured blooms as possible into the picture. The best effects are undoubtedly achieved in subtle tones of the same colour or combinations of pastel shades. The colours will be true to life only if the subject is given the exact exposure. This means that all exposures should be measured with an accurately calibrated exposure meter. Where there is a mixture of colours in the scene, the exposure may have to be measured within inches of the most important colour to ensure that it is reproduced correctly.

P.J.

FLOW PHOTOGRAPHY. Method of studying phenomena of a transient nature which are difficult to observe normally. This covers subjects whose activity is too fast for the eye and brain to perceive as discrete parts of a sequence, or subjects whose rate of change are too slow for the retinal memory to carry an image in the brain long enough to compare with the next impression.

Still Photography of Liquids. Water flow can be recorded and studied with the still camera, to show surface and depth flow, and the effect of water flow on, say, the bed of a river. For this work one might employ candles, electric floats; positive, neutral, or negative buoyancy particles; dyes; or air bubbles. The last, due to their positive buoyancy should be restricted to use in water tunnels where the water flows upward through the working section. Using candle floats (birthday cake), or electric floats (comprising a miniature battery and miniature bulb in a buoyant waterproof case) and an interrupter in front of the camera lens, it is possible to record the direction and velocity of surface flow. For depth flow a deep draught float is needed.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The interrupter could be a five-bladed fan revolving at 1 rev per 10 seconds to give exposures of 1 second every other 1 second. The camera shutter is left open for the appropriate time. The result shows a series of varying length tracks indicating the velocity and direction of the floats over the water. Without the interrupter the result shows various flow patterns.

Under water or through a glass-sided tank, neutral and negative buoyancy particles will show flow stream phenomena between the surface and the disturbed flow associated with the bed of the model or river, etc. Dyes and air bubbles coupled with short or long exposures show dispersion of flow, and limits of disturbances.

Still Photography of Gases. Since gases are compressible it is possible to make use of optical techniques which are sensitive to variations of refractive index in the gas. Schlieren and interferometric systems make it possible to record shock waves and other disturbances associated with gases passing an object at high speed. The sensitivity of a Schlieren system can be varied; e.g. by altering the position of the source or knife-edge or the use of graded glass filters. Colour materials can be used with a multi-colour filter, say red, green and blue, where green is in the middle and gives the picture its background colour. Light rays passing through the system may be bent due to refraction and pass through the red or blue portions indicating high or low densities according to the orientation of the filter.

The interferometric method shows refractive index variations as fringes, and each fringe indicates a specific value.

A multi-spark light source can be used in conjunction with a Schlieren system. The spark sources are arranged in a circle and fired successively. This produces a plate with a series of small images in a circle. The duration of the spark and the interval between the sparks are measured in micro-seconds. Thus it is possible to study a hypersonic shock front for a brief instant.

Long exposures, or many short exposures on one plate, in conjunction with back-illuminated smoke or vapour, show density variations and total limits of pollution from chimneys and ship funnels. They can equally show up the flow of air over car bodies, ships, aircraft, buildings and industrial sites.

Time-lapse Cinematography in Liquids. Time-lapse is one of the few methods of recording phenomena that enable us to analyze and visualize changes occurring too slowly to see. By making the interval between exposures many seconds, minutes, or even hours, the action is speeded up many times on projection at normal speed (16 or 24 frames per second)—e.g. a plant growing from seed to full bloom in three minutes.

To study flow in liquids, the same floats or particles already mentioned may be used. By projecting the film at normal speed it is possible to visualize form, etc. and also to analyze the film frame by frame. This is most easily done with a special analyzer which measures the position of a float against a fixed datum and transfers the information to punched tape. Later the punched tape can set out the information in tabular form, or draw graphs of the float behaviour and flow velocities. It is also at this stage that variables can be fed into the computer to save further mathematics later.

Time-lapse will show the effects of flow, e.g. the drift of a sand-bar due to water flowing over it.

A method of studying flow on the full scale, e.g. currents, etc., inside a large harbour, is to place suitable radar reflectors in the water. These are picked up by the aerial and imaged on the radar screen as dots. A cine camera arranged to take a picture (e.g. one a minute) of the radar screen, might—on projection at normal speed—show in the harbour unsuspected currents, eddies, etc.

Time-lapse Cinematography in Gases. By taking a picture of the sky every few seconds meteorologists have been able to study cloud formations, etc. An automatic iris control fitted to the camera lens coupled to the exposure meter ensures even exposure throughout the film.

Normal and High-speed Cinematography in liquids. Normal and high speed cine are considered together, since it is not unreasonable to film a model at model speed for analysis and to film the same model at a higher speed to simulate the full scale for visualization, e.g. a model boat in waves. The relationship between camera projection speed is given by the equation:

$$\sqrt{\text{model scale}} \times \text{projection speed f.p.s.} = \text{camera speed f.p.s.}$$

For example, for a boat model on a scale of 1 : 64, we have:

$$\sqrt{64} = 8 \times 24 \text{ f.p.s.} = 192 \text{ f.p.s.}$$

Thus a film shot at 192 f.p.s. will give the impression of a full size ship at sea if it is projected at 24 f.p.s.

Suitable markers (e.g. lighted torch bulbs) fixed to the model and to rigid points in the background will provide datum points in the picture area from which measurements may be taken, or allow assessment on an automatic analyzer.

Neutrally buoyant particles placed in the flow stream ahead of a model will show the stream lines and disturbed regions round a ship's hull, piers, etc. With two cameras mounted at 90° to each other it is possible to plot X, Y and Z co-ordinates of the positions of these markers frame by frame for a three-dimensional representation.

Underwater records are obtained by filming through a glass window. Alternatively, one end of a periscope may be placed in the water, with the camera fixed to the other end above water. Other possibilities are an underwater camera—

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

either fixed, or remotely controlled with a closed-circuit T.V. viewfinder.

Stroboscopic light sources are valuable for studying oscillatory or cyclic phenomena. Putting the stroboscopic light source slightly out of phase with the subject, e.g. a propellor, produces a form of mock high-speed cinematography if filmed at normal speed.

Normal and High-speed Cinematography in Gases. Cine cameras in conjunction with Schlieren systems enable flow patterns and shock waves to be studied. The camera taking speed is ascertained linearly in relation to smoke plumes or streams in a wind tunnel. For example, a factory chimney model may be set up with a ratio of full scale to model scale wind velocities of 5 : 1. For projection at 24 f.p.s., a camera speed 120 f.p.s. will give full scale simulation.

The combustion of fuel in engines can be studied with a high-speed camera, filming a special engine with a toughened glass cylinder wall or cylinder head.

High-speed cameras usually have a built-in time base film marker, which leaves a series of dashes on the margin of the film. The frequency of the marker might be 1,000 c.p.s. in which case a film showing one dash per three frames would have been taken at 3,000 f.p.s. A.W.G.

FLUORESCENCE. As a rule, when materials absorb light they convert it into kinetic energy, or heat. But some substances re-emit part of it as light of a longer wavelength. Such substances are said to fluoresce. Dyes, like fluorescein, eosin, and rhodamine, will fluoresce in solution. Zinc and cadmium sulphides, suitably activated with other metals, will also fluoresce. These, or similar substances, are used for coating the glass tubes of fluorescent lights. Certain substances will absorb invisible rays of ultra-violet light and convert it into light of a visible wavelength. Sometimes the radiation goes on even after the exciting light has been removed. This kind of radiation is known as phosphorescence.

The familiar fluorescent lighting is produced by coating a mercury vapour tube with substances that fluoresce under the influence of ultra-violet radiation. The invisible ultra-violet rays are converted into visible light, and by a suitable choice of coating material the colour of the resultant light can be varied throughout a range of "daylight" tints.

Fluorescence enables some materials to be photographed by invisible radiations when other non-fluorescing substances remain invisible. Among substances that fluoresce, some do so more strongly than others. This provides a valuable means of creating contrast differences which do not exist in ordinary light.

Apart from its use in radiography (fluorography) fluorescence photography can reveal things that would otherwise be invisible—e.g., the presence of two kinds of ink, which fluoresce differently, in a falsified document. The technique is used in a number of different fields of photography and scientific observation.

See also: *Fluorescent lamp; Forgeries; Luminescence; Ultra-violet and fluorescence photography.*

FLUORESCENT INK. Printing ink containing a fluorescent pigment or dye that absorbs short wavelength, ultra-violet and blue-violet rays (to which the eye is comparatively insensitive) and re-radiates their energy as light rays of longer wavelength (yellow to red). On dull, grey days or in poor light, such pigments (largely used for poster work) appear brighter to the eye than a non-fluorescing pigment and also to the photographic emulsion of those high-speed panchromatic films which are over-sensitive to red. This effect can be compensated for, if necessary, by the use of a filter complementary in colour to the fluorescent ink.

See also: *Paintings and drawings.*

FLUORESCENT LAMP. Type of vapour discharge lamp in which the glass envelope is coated with a substance capable of effective fluorescence. The rays emitted by the lamp cause this coating to fluoresce.

Fluorescent lamps are normally tubular with a contact cap at each end; this cap may be bi-pin, bayonet or raised contact. For convenience the tubes are usually mounted or clipped into holders which also serve as trough reflectors or diffusers.

Quality of Light. By choice of the coating substances used, fluorescent tubes can be made to emit light of different but very constant colour temperatures; the more commonly manufactured range is natural daylight and warm-white. For accurate colour-matching, a special tube is also made.

Fluorescent lights are very efficient in their use of electricity because they turn so little of it into wasteful heat. A tube consuming 40 watts gives about the same amount of light as an ordinary domestic tungsten filament lamp of 150 watts. The light is soft, low intensity, and diffused, since the tube may be anything from two to eight feet in length. For this reason the photographic applications are limited to general illumination, in particular, of the copy board in process and document photography, and of such subjects as oil paintings.

Operation. Fluorescent lamps may be run off either an A.C. or D.C. mains supply.

On A.C. the tubes will flicker at double the frequency of the supply and are not suitable for instantaneous exposures of a shorter duration than two cycles—i.e., of anything less than 1/25 second with a 50 cycles per second supply. If a steady light is essential—as in cinematography—three tubes may be connected across the phases of a three-phase supply.

CC-BY-NC-SA. Indian Institute of Technology Madras. Digital Preservation Foundation, Chandigarh

Special control gear is required with all arc and vapour discharge lightings because the internal resistance is not constant. For D.C. operation a ballast resistance must be connected in the circuit and, since this accounts for about half the total consumption, it lowers the efficiency of the lamp. On an A.C. supply the lamp must be connected in series with a choke to limit the current. Where the supply voltage is too high or too low for the tube, a reactive transformer is used in place of the choke. In addition to a choke or transformer, the circuit may also need one or more condensers to compensate for the inductive load and maintain the power factor of the supply.

There are two ways of starting up a fluorescent lamp. The commonest method is by passing a starting current through a heating filament inside the tube, and the other by applying an initial voltage high enough to ionize the gas in the tube. The first type of tube is called a hot cathode; it is used for practically all domestic and public building illumination and for subject lighting in photography. The second, known as cold cathode illumination, is used in photography principally as an enlarging light in the form of a compact grid extending over the whole of the negative area.

Luminous Panel Light. Certain substances emit visible light rays when placed in a high voltage alternating current field. Materials of this type form the basis of a special type of luminous panel lighting. A layer of the material is sandwiched between a layer of metal foil and a layer of transparent conducting plastic. The metal side of the sandwich is supported on an insulating base and the transparent side is covered with a sheet of glass or transparent insulating plastic. When an alternating current at 230 volts is applied to the conducting layers, the intermediate coating glows with a brightness of about ½ foot lambert. The light emission can be increased by applying a higher voltage, and the colour of the light can be varied according to the composition of the coating material or by incorporating a suitable filter in the transparent layer. The total amount of light available depends on the area of the panel.

Luminous panel lighting has been applied on a limited scale as a safelight for both panchromatic materials and enlarging papers, and for luminous notices and clock faces in photographic material coating rooms. This form of lighting has the advantage of being practically cold and therefore exceptionally efficient (because practically all the electrical energy is converted into light).

Such luminescent panels are also coming into use as a light source for contact printing and copying. In a luminescent contact printer the negative and the positive paper are pressed into contact with the luminous panel. Although the actual brightness of the panel is not very great, the light output is fully utilized by the direct contact with the printing material and hence reasonable printing exposures become possible.

Luminous panels on their own have also been used for document copying. Here again the panel is pressed into contact with the sensitive material and the document or printed matter to be copied. If the latter is a page in a book, the panel—which is thin enough for the purpose—may be placed inside the book and the latter closed to provide the necessary contact pressure. Printing here is by the usual reflex process, with the front of the document paper in contact with the original and the back pressed against the luminous panel. Both the conventional transfer and negative-positive copying processes are suitable for this purpose. F.P.

FLUORESCENT WHITES. Some photographic papers are treated in manufacture with a fluorescent dye to increase the effective reflectivity of the base. This adds brilliance to the highlights of the photograph, particularly when it is viewed in daylight. This is because daylight is rich in the ultra-violet light which causes the dye to fluoresce.

There is one great disadvantage of this type of base. If photographs made on it are intended for reproduction, the highlights must not be worked up with ordinary process white. A special type of fluorescent process white must be used, otherwise the retouching will show clearly on the finished half-tone reproduction although invisible in the original print.

FLUOROGRAPHY. Process of photographing the visible image produced by the impact of invisible radiations on a fluorescent screen. There are two methods of fluorography—contact and optical. In the contact method, the sensitive photographic material is pressed into contact with the screen. In the optical method, the image is photographed by setting up a camera in front of the screen.

The commonest application of optical fluorography is in mass miniature radiography.

FLUOROTYPE. A paper process invented by Robert Hunt in 1844. The paper was prepared with sodium fluoride and developed with protosulphate of iron. In spite of the reasonably short exposure of half a minute, the fluorotype did not come into general use.

FLYING SPOT SCANNER. System in which an electron beam scans an image by moving over it in the form of a spot of light. This spot can expose an image on a sensitive surface if the spot is made to vary in intensity on going through a normal negative or positive. Such a

set-up is used in electronic printing systems. If the spot of the electron beam is made to vary in intensity while passing over different points of a phosphorescent layer, an image can be made visible to an observer in front of the screen. The scanning speed must then be high enough to cover the whole image within the period of persistence of vision. This is the use of a flying spot scanner in assembling an image on a television picture tube.

***f*-NUMBER.** Numerical expression of the relative aperture of a lens at its different stops. The *f*-number is equal to the focal length divided by the effective diameter of the lens opening, and is written in various forms—e.g., *f* 8, *f*/8, 1 : 8, etc. When focused on infinity, all lenses stopped down to the same *f*-number produce images of equal illumination (apart from differences due to varying reflection losses). For a given shutter speed, a given *f*-number always corresponds to the same exposure.

See also: *Aperture; Diaphragm.*

FOCAL LENGTH. Term in optics referring to the distance from the plane in which the lens forms an image of objects at infinity to the node of emission. It is important in photography because it decides the scale of the image (the longer the focal length, the larger the image) and the extension of the camera (a longer focal length calls for a greater amount of camera extension). More precisely, it is the equivalent focal length defined by the relation $f = y/\tan \beta$ where β is the angular subtense of a small object of image height y.

The focal length of a lens is usually engraved on the mount thus: $f = 90$ mm. This should not be confused with the *f*-number.

See also: *Lens.*

FOCAL PLANE. Imaginary plane on which a lens forms a sharp image when correctly focused. For sharp pictures the emulsion surface of the plate or film in a camera must be accurately positioned in the focal plane of the taking lens.

See also: *Lens.*

FOCAL PLANE SHUTTER. Shutter consisting of one or more roller blinds of fabric or metal, having a generally variable slit which moves across the back of the camera when the release is pressed and exposes the sensitized material progressively. This type of shutter is mounted as close as possible to the surface of the sensitized material—i.e., to the focal plane. In that position it is most efficient, and also gives consistent exposures with lenses of varying focal lengths. The focal plane shutter was invented by William England, 1861; re-introduced by B. J. Edwards, 1879, and included in the camera patented by Ottomar Anschütz, 1888, to whom its invention is usually erroneously attributed.

See also: *Shutter.*

FOCAL POINT. Point of intersection of all rays of light transmitted by a lens from a given object point. When the object is at infinity, and the incident rays are parallel to the lens axis, the image is the principal focal point and lies on the axis of the lens.

See also: *Lens.*

FOCUS. Point of convergence. In optics it is the point on the optical axis of a lens or mirror through which all rays of light parallel to the axis pass after refraction (lens) or reflection (mirror).

See also: *Lens; Mirror.*

FOCUSING

The camera lens forms an image of the objects in front of it on the film or plate in the back of the camera, but the image is sharp only when the distance between the lens and the film is correct. What the correct distance is depends on the focal length of the lens and how far away the object is. Adjusting the camera to this distance is known as focusing.

All but the cheapest cameras have some means of focusing. Very cheap box cameras have fixed focus lenses. They work at small apertures and so have sufficient depth of field —from about 10 feet to infinity—to give a sharp picture without focusing. Such cameras are only intended to photograph subjects more than 10 feet away, except when using supplementary lenses.

There are two ways of adjusting the image sharpness: by changing the actual distance between the lens and the film, and by changing the focal length of the lens.

There are several ways of changing the lens-film distance.

On most miniature cameras, for example, it is done by a helical focusing mount in which the lens can be rotated to screw it towards or away from the film.

In most plate cameras and many twin lens reflexes the whole lens panel is moved forward or backward by a rack and pinion.

In many field and technical cameras the actual film plane is moved forward or backward for focusing.

Again, the focal length of the lens may be altered by increasing or decreasing the separation between the lens elements. Usually the front cell of the lens moves in or out in a screwed mount, and the method is known as front cell focusing. Many of the simpler modern cameras have front cell focusing.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

PRINCIPLE OF FOCUSING. When a lens is focused at infinity, rays from a very distant object point converge to a corresponding image point a given distance behind the lens in the focal plane. As the object point is brought nearer, the image point moves farther away from the lens: the lens-film distance must be increased to obtain a sharp image of close objects.

In effect the use of positive supplementary lenses is simply another way of shortening the focal length of the camera lens thus enabling it to focus on close-up objects within the limits of the camera extension.

Direct Screen Focusing. In one of the oldest and surest methods of focusing, the image is observed on a ground glass focusing screen in the back of the camera, and the lens is adjusted until the subject is sharp. The ground glass screen is then replaced by the sensitive material in the film or plate holder. It is essential for the surface of the sensitive material to lie in exactly the same plane as the ground surface of the focusing screen. This calls for accurate construction of the plate holder and focusing screen slide. Given this, direct screen focusing is extremely reliable.

The focusing screen not only shows the sharpness of the image, but also the exact picture that will be photographed on the negative. It is, therefore, a means of composing as well as focusing.

The drawbacks of direct screen focusing are that it is slow and the image appears upside down on the screen. As the image must not move while the focusing screen slide is changed for the plate or film holder, it is limited to more or less still subjects, and the camera must be mounted on a tripod.

Reflex Focusing. In the reflex camera the image is focused on a horizontal screen set in the top of the camera. The image is projected on to it by a mirror behind the lens. When the shutter release is pressed the mirror swings out of the way and immediately afterwards the shutter opens and exposes the film or plate in the back of the camera. The time lag between focusing and exposure is reduced to the time taken by the mirror to move out of the way—a fraction of a second.

Reflex focusing has all the advantages of the ordinary focusing screen but once the image is focused the exposure can be made right away. This means that the camera can be held in the hand and used for taking moving subjects.

Reflex cameras have one great drawback: it is not always convenient to use the full aperture of the lens, and when it has to be stopped down beyond about *f* 6·3 the picture on the screen might become too dim to be of any use.

This disadvantage has been overcome in most modern cameras by use of a pre-set iris control. The aperture required for the exposure is selected but not actually adjusted. This allows the lens to be used at full aperture for focusing. When the shutter release is then pressed, the iris automatically closes to the selected aperture before the shutter opens.

All the focusing aids used with the ordinary focusing camera can be applied to the reflex screen.

Reflex cameras usually have a built-in focusing magnifier, while a collapsible hood takes the place of the focusing cloth.

A further feature of a reflex screen image is that it is reversed left-to-right. This mainly affects the use of the screen for arranging the subject and following movement. The majority of current miniature reflexes incorporate an optical reversing system such as a pentaprism to yield an upright and right-way-round image for eye-level viewing.

Some miniature single-lens reflex designs have also succeeded in eliminating yet another disadvantage of the moving mirror system: the disappearing image. In these models the mirror

REFLEX FOCUSING. In the reflex camera a movable mirror deflects the rays from the lens on to a ground glass screen at the top. This shows the exact sharpness of the image as it would appear on the film. The mirror swings away for exposure.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

returns to its viewing position immediately after the exposure so that the subject continues to be visible once the picture is taken.

Twin-Lens Reflex Focusing. Twin-lens reflex cameras really consist of two camera systems built one above the other. The bottom camera is used solely for taking the picture, while the top one is used quite independently for viewing and focusing. The two camera lenses are, however, geared together, so that what is sharp on the upper reflex focusing screen will also be sharp on the film behind the lower lens.

The twin lens principle has several advantages: there is no time lag between focusing and exposure; the focusing (and viewing) lens always remains at full aperture (in fact, the aperture of the focusing lens is often larger than that of the camera lens, giving more critical focusing and a brighter image).

But there are also drawbacks: as there are two lenses, focusing accessories such as supplementary lenses must be bought in matched pairs instead of singly; the twin-lens reflex camera is subject to parallax error.

TWIN LENS REFLEX FOCUSING. Instead of the movable mirror of the single lens reflex, the twin lens reflex has a second focusing camera with a matched lens coupled to that of the taking camera so that both are focused in unison.

Aids to Screen Focusing. There are a number of aids to exact focusing on a screen.

The image can be focused more sharply with the help of a focusing magnifier. This is nothing more than a simple magnifying glass, often mounted in a suitable holder a few inches from the focusing screen.

For accurate work, particularly with the focusing magnifier, the ordinary glass screen is too coarse; the grain of the screen breaks up the image and lowers its resolution.

Flashed opal glass is a better material; it gives an image that is dimmer, but practically grainless. At the same time, the flashed layer has a certain thickness (the matt surface of a ground glass screen has practically none), and this can introduce its own focusing errors.

An ordinary glass plate coated with an emulsion of fine rice starch or barium sulphate in gelatin also gives a very fine screen.

Clear Spot (Aerial) Focusing. The image formed in the plane of the focusing screen can be observed directly through a magnifier without any assistance from the screen itself. If a disc of clear glass is cemented on the ground surface with Canada balsam it forms a transparent spot where the image can be focused in this way. This method of focusing is known as clear spot or aerial focusing.

It is essential, however, for the aerial image, seen in the clear spot to lie in the same plane as the surface of the ground glass. So the glass disc is cemented in position over a cross pencilled on the focusing screen or better still a couple of fine hairs. These indicate the exact plane in which the image must be brought to a sharp focus.

The magnifier is first focused on the hairs and fixed in that position. Next the lens is adjusted until a sharp image appears in the same plane as the hairs.

In practice it is not always easy to keep the eye focused on the two things at the same time. But by moving the head slightly from side to side, it is easy to see when the hairs and the sharp image lie in the same plane. If they are not, one will appear to move in relation to the other as the head is moved; if they are in exact register, they will move as one. This extension of aerial focusing is known as parallax focusing.

A pair of crossed glass wedges, recessed into the focusing screen so that the crossing point is exactly level with the focusing surface, can show up such a parallax effect automatically. When the image is not exactly focused, it appears split across the dividing line between the wedges, with the two halves displaced relative to each other. Focusing in this way is visually the same as with a split-image rangefinder. Many current miniature reflex cameras incorporate this feature.

Double Image Focusing. When the lens is not focused properly, different parts form images in slightly different positions on the screen. The separate images may be fairly sharp but they all combine to form a blur.

If a strip of opaque material is placed across the centre of the lens, about one-third of the lens diameter in width, it will leave two images, formed by the left hand and right hand segments of the lens. These images will be sharper than the image formed by the whole lens, but they will be out of register unless the lens is correctly focused.

The strip must be as close to the front surface of the lens as possible. The strip must, of course, be removed before the exposure.

It is nearly always better to focus with the camera lens at its largest aperture, and stop down for the exposure later if necessary. At large apertures the depth of focus is small, so the transition from sharp to unsharp is much more rapid. The image is brighter and easier to see. An exception to this method is when using certain lenses, that shift their focus when the aperture is decreased.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

BRACKETING. Top: *Observe the image on the focusing screen and start from a setting with the near limit of the subject unsharp.* Centre: *Continue until the far part begins to become unsharp.* Bottom: *Set the focusing control midway between the positions corresponding to the beginning of unsharpness at each end.*

Bracketing. The image often appears reasonably sharp anywhere inside a certain range of focusing movement. This is because the resolution of the screen and possibly the eyesight of the operator limit the degree of sharpness that can be appreciated. For most practical purposes it is enough to narrow down this range to a minimum by trial and then to set the focusing adjustment midway between the front and rear limits within which the image looks equally sharp.

This method of focusing is called bracketing.

Accurate focusing must take into account the whole of the image, not merely the central area. No lens is good enough to give the same standard of sharpness all over the plate; it is often impossible to focus the image sharply at the centre and the edges of the screen at the same time. When this happens, the bracketing method is used to set the lens midway between the positions that give maximum sharpness to the centre and the edges of the image. In this position over-all sharpness can then be achieved by stopping down the lens.

Focusing by Scale. Nearly every camera has a focusing scale, even if it also has a focusing screen or a rangefinder. The scale is useful for action photographs.

Where the whole lens is moved for focusing, the distance through which it must be moved forward from its infinity position to focus it on a nearer object is given by the equation.

$$d = \frac{F^2}{u - F}$$

where d = forward shift of lens from infinity position
F = focal length of lens
u = distance of object from lens.

In practice, the exact focal length of the camera lens is not very simple to measure. The value marked on the lens itself is usually good enough, but is not always accurate. Individual lenses may deviate slightly from their nominal focal length.

By focusing first on infinity—i.e., a very distant object—and on an object say 3 feet away, the exact focal length can be calculated from the equation:

$$F = \frac{dU}{V}$$

where F = focal length of camera lens
d = lens extension for close-up focus (i.e., difference between infinity and close-up settings)
U = size of object
V = size of image.

All measurements must be in the same units; e.g., all in inches, or all in centimetres.

With front-cell focusing lenses, calibration of the scale is much more complicated, and depends very much on the construction of the lens. The amateur can only calibrate or check the focusing scale of such a lens by trial and error.

In most cases the lens-to-film distance is so small in comparison with the subject distance, that it does not matter whether the subject distance is measured from the front or the back of the camera. But for accurate work, particularly for close-ups, the subject distance should be measured from the front of the lens, or still more exactly from the forward nodal point (approximately one-third of the thickness of the lens from its front surface).

A few cameras, however, carry a warning that all distances must be measured from the plane of the film.

Where the camera is focused by scale, the actual subject distance must either be measured separately, or estimated (e.g., by assessing the size of an average person in the viewfinder).

With action subjects where the distance may change suddenly, the focusing scale is best used in conjunction with a depth of field indicator to select suitable zone focus settings rather than exact subject distances.

Rangefinder Focusing. In focusing by range-

RANGEFINDER FOCUSING. The rangefinder measures the subject distance by the convergence of two rays from the ends of a fixed base, as observed by the coincidence of two images.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

finder, the photographer either sets the lens focusing scale to the distance given by the rangefinder (where a supplementary, or non-coupled rangefinder is used) or the act of adjusting the rangefinder automatically focuses the lens on the subject (where the camera has coupled rangefinder focusing).

In any case, the rangefinder must first be adjusted to read the subject distance. Generally this means adjusting the lens (with a coupled rangefinder) or moving a lever or turning a wheel to produce coincidence between either two overlapping images or two halves of a split image. The point of coincidence is easy to recognize in good light but it may be impossible when the light is poor.

It always helps if the part of the subject to be focused on includes a well-defined edge—e.g., the profile of a face, a gatepost, or the branch of a tree. If the important area contains no such clear line, as for instance when the subject is a fluffy kitten on a plain carpet, then the finder should be ranged on the edge of some other convenient object at the same distance.

Where, in addition to the subject itself, objects in front and behind must also be rendered sharply, a single reading of the rangefinder is not enough. It is first set for the nearest object that must appear sharp, and the distance read off the scale. The same thing is done for the most distant sharp object. The depth of field scale is then examined to find what lens aperture and focusing setting will just include these distances, and the camera is adjusted accordingly.

The distance on the focusing scale under these conditions may not be the same as the rangefinder reading of the subject distance, but it will be the setting that includes the subject in the field governed sharply by the lens.

Close-up Focusing. With near subjects accurate focusing becomes specially important. There the ideal method is screen focusing on a plate or reflex camera.

Various accessories are available for other camera types to establish the correct subject distance. The simplest may take the form of distance gauges for use with specific supplementary lenses or extension tubes. More elaborate systems feature accessory rangefinders and rangefinder adaptors for cameras fitted with a rangefinder, or reflex housings and focusing stages to convert a miniature camera for ground glass screen focusing.

Uncorrected Lens Adjustment. A lens that has not been corrected for chromatic aberration may still be used for normal photography by moving the lens nearer to the plate after focusing the image visually.

The yellow rays are visually the strongest when focusing the image; when these are sharp on the focusing screen, the blue, photographically more active, rays are focused sharply on a plane slightly in front of the visual image. The exact position of the blue-sharp plane must be found by trial and error, but for most chromatically uncorrected lenses it is displaced approximately 1/40th of the distance of the plate from the lens.

To arrive at a reasonable point for starting experiments, the image should be focused visually—preferably with a magnifier.

The camera extension is then measured, and the lens moved back from 1/30 to 1/40 of the distance. A series of exposures should then be made at, in front of, and behind this distance to find the point of maximum sharpness. For the final exposure the lens should be worked at a very small aperture.

As only the image formed by the blue rays is in focus, all the other unsharp rays must be prevented from registering on the plate. This means either using a plate that is insensitive to all but blue rays—i.e., a blue-sensitive process type plate, or fitting a deep blue filter in front of the lens to allow only blue rays to reach the plate. Either of these measures makes for long exposures so that the method is only suitable for still subjects. L.A.M.

FOCUSING (AUTOMATIC)

Method of adjusting the sharpness of an image without visually judging it. Strictly speaking, fully automatic focusing also involves a system of getting an unsharp image sharp on its own by suitable servo circuits. This term is sometimes also applied to the various systems of rangefinder coupled focusing in which setting the rangefinder for a given distance automatically focuses the lens.

This again however is not really automatic, since it involves both visual judgement (though not directly of image sharpness) and manual control.

Automatic focusing systems require two stages: measurement of the sharpness of the image, and a provision for evaluating this measurement and using it to adjust a focusing mechanism for maximum sharpness.

Of the various sharpness measurement methods proposed the only one in practical use nowadays relies on measurement of image contrast. The contrast of a sharp image of a given subject is higher than the contrast of the same image when it is out of focus.

An instrument which is able to measure the light distribution in the image, and compare it

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

IMAGE SHARPNESS AND LIGHT DISTRIBUTION. Top: *When the image of a pattern O is projected on a screen, it appears sharpest (C) in the focal plane (3) of the lens. In the plane 2 (and 4) the image is partly blurred (B); in the completely defocused planes 1 and 5 it tends to be a uniform area of brightness (A).* Bottom: *The brightness distribution of these images, if measured in a plane across the bars, corresponds to the three curves A, B, and C, oscillating to varying degrees between E and F about the mean level A.*

for a sharp and an unsharp picture, can therefore also measure sharpness. This may be done with a dectector which registers independently adjacent light intensities of an image, and which does so in a non-linear fashion. That is to say, it must react disproportionately to different light intensities, like a photographic emulsion or a cadmium sulphide photo conductor. Such a photo conductor is in fact used in virtually all contrast automatic focusing systems.

On plotting the output of the cell while the image passes from unsharp through the plane of maximum sharpness to unsharp again, the current follows a fairly straight curve with a pronounced dip as the image becomes sharp, and a rise as the image becomes unsharp again.

Measuring Instruments. This change in output of the photo cell can be used to monitor the sharpness of an image without actually observing it. One instrument of this kind uses two photo cells. One of them has a diffusing screen in front of it to compare the output corresponding to a completely defocused image with the output of the second cell responding to the change in sharpness. The two cells are connected in a bridge circuit, the output of which feeds a galvanometer or ammeter. The deflection on the meter dial is greatest when the image is at its point of maximum sharpness.

Instruments of this nature exist both for camera focusing and for enlarging. In the first case a probe containing the photo cells is placed in the image plane of the camera (or on the focusing screen); in the second case it is placed on the enlarger baseboard. To ensure maximum contrast of the sharp subject (and hence greatest sensitivity of the instrument) an artificial subject or target is sometimes used, consisting of a uniform pattern of black-and-white lines or dots, such as a ruled halftone screen. This is placed in the negative carrier of the enlarger or in the subject plane of the camera during the focusing operation.

Automatic Ranging Systems. This principle of sharpness measurement can be extended in

LINEAR AND NON-LINEAR RESPONSE. Top: *A linear responding measuring instrument reacts to brightnesses strictly in proportion to their intensity (dotted curve). A non-linear receptor (for example a photo-conductive surface) does not respond to brightness in proportion to its intensity (solid curve).* Bottom: *Great brightness variations (greatest contrast) correspond to the sharpest image. When a non-linear receptor such as a photocell moves through the different planes of an image from unsharp through sharp to unsharp again, the output drops distinctly in the plane of maximum sharpness.*

BALANCED CELL SHARPNESS METER. Here two photocells measure the light simultaneously in the image plane. One cell has a diffuser in front of it. The two cells are connected in a bridge circuit so that brightness variations affecting both cells (varying distance from the lens, etc.) cancel each other out. The resulting output of the circuit can be read on a meter dial so that the maximum dial reading corresponds to the maximum sharpness. A, high contrast target. B, lens. C, image in focal plane. D, measuring photocell. E, balancing photocell with diffuser (so that the cell is not affected by changes in focus). F, bridge circuit. G, meter dial.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

various ways to provide a fully automatic focusing system. There the output of the photo conductor cell is continuously monitored and used to drive a servo motor. The latter adjusts the focus to maximum sharpness.

One method is to have two such photo cell systems positioned in front of and behind the plane of maximum sharpness. The differential outputs of the two sensing systems are in turn connected in a bridge circuit. When the plane of maximum sharpness is exactly in the middle between the two sensing systems, their output is exactly balanced. As the plane comes nearer the one or the other cell pair, this system produces a signal. The sign of the signal depends on the direction in which the plane of maximum sharpness has moved. This signal can then be used to drive a servo motor to restore the image plane (for example by refocusing the lens) into the exact halfway position.

A second ranging system uses a single photo cell (or cluster of cells) which oscillates to and fro at a fixed frequency through a series of planes which includes the plane of maximum sharpness. During each passage through the sharp plane, the output drop of the cell shows itself as a signal pulse. If the sharp plane is exactly in the centre of the oscillation range, the output takes the form of a signal of a regular pulse frequency. When the sharpest plane is not in the middle of the oscillation range, the pulse signal becomes unsymmetrical. The rate of change of the signal frequency is then measured and used to activate a servo motor which readjusts the position of the lens or the image plane. This permits focusing not only of a static but also of a moving image.

A third way is to monitor the output of a single photo-conductive cell as it passes from a position of maximum unsharpness to maximum sharpness. While the output drop in this case is fairly gradual, electronic differentiation can yield a steep curve indicating the rate of change of output. We can then determine fairly reliably the point of the maximum rate of change—i.e. the point of maximum sharpness.

Such a system has been used in a camera. The cell there moves through the image planes of a secondary optical system, with the movement geared to the motor-driven focusing movement. As the cell reaches the position of maximum image sharpness, the focusing motor cuts out at the right point, with the lens accurately focused. The field of view of the sensing optical system in this case only takes in a small portion of the picture area, to permit focusing on selected subject portions. The working of this system depends on having a subject of sufficient detail contrast within the image area being measured.

L.A.M.

AUTOMATIC FOCUSING CAMERA. A photocell is driven through the focal plane of an optical system and the cell output monitored electronically so as to switch off the driving motor when the cell has reached the plane of maximum sharpness. The motor also shifts the camera lens to produce a sharp image on the film. A, automatic gain control (to compensate for subjects of different brightness). B, optical system of camera. C, driving motor for focusing movement (camera lens and photocell). D, optical system of photocell. E, cadmium sulphide cell. F, electronic stages of system. G, switching stage to control motor.

THE OSCILLATING OPTICAL RANGER. Top: If a photocell oscillates to and fro across the focal plane of an image, its drop in output in the focal plane gives rise to a signal pulse that can be observed as a wave form on an oscilloscope screen. Centre: If the focal plane is exactly in the mid-point 3 of the oscillating cycle, the wave form has a regular shape. The peaks of the pulses occur at the positions corresponding to the plane 3, and the troughs at the positions corresponding to planes 1 and 5 (maximum unsharpness). Bottom: If the sharpest plane is not in the mid-point of the oscillating movement of the cell, the wave form changes and shows up the lack of sharpness. This change in the pulse frequency can also drive for instance a motor to move the lens and restore maximum sharpness in the central image plane.

FOCUSING CLOTH. Square of opaque cloth, often lined with black velvet, which is draped around the focusing screen and over the head and shoulders of the photographer to shut out all light but that of the image on the ground glass. When not in use it provides a convenient light-tight wrapper for the loaded plate holder.

CC-0. Jangamwadi Math Collection. Digital Preservation Foundation, Chandigarh

FOCUSING HOOD. Folding hood, usually of metal, surrounding the focusing screen of waist-level reflex cameras to shield off light for a clearer view of the screen image. Often incorporates a fold-away magnifying lens (focusing magnifier) to permit precise focusing of an enlarged centre section.

FOCUSING MECHANISM

All cameras (apart from the fixed focus types) must have some means of focusing—i.e. of setting the lens at the correct distance from the plate to give a sharp image of the subject to be photographed. There are several ways of doing this; any one of them to be efficient must fulfil the following requirements: it must be free from backlash and play, and it must maintain the lens rigidly in a plane parallel with that of the sensitive material.

Most, but not all, focusing arrangements are associated with a scale that shows, for every position of the lens, the distance in feet or metres from the camera at which objects will be sharp on the negative.

Rack and Pinion Focusing. Most of the older types of camera, and almost all cameras taking half-plate or larger negatives, focus by rack and pinion. The lens, in such cases, is attached to a panel strutted at right angles to a movable slide running in guides on the baseboard. A brass strip let in to the underside of the slide carries teeth that engage with a pinion turned by a thumb-wheel at the side of the baseboard. Turning the thumb-wheel moves the slide in or out. On large cameras the slide is moved by a rack and pinion at each side of the baseboard to prevent it from binding in the guides.

Generally, the lens panel can be set up and locked anywhere along the slide, and once it is roughly in position the rack and pinion focusing is used for the final adjustment. This arrangement has the added merit of doubling the available camera extension and also providing for lenses of long and short focal length.

Rack and pinion focusing is satisfactory where the amount of lens movement is relatively large—i.e. on say, a whole-plate field camera where the lens moves forward nearly four inches from the infinity position to focus on 3 feet. But it is not accurate enough to be satisfactory on smaller cameras where, for instance, a 2 ins. lens moves forward only a little more than one tenth of an inch from infinity to focus on 3 feet. To give comparably fine adjustment on the smaller camera the diameter and tooth sizes of the pinion would have to be scaled down so far that the parts would not be strong enough for their work.

Other Methods of Shifting the Lens Panel. On process and copying cameras, the rack and pinion arrangement is sometimes discarded for a nut and leadscrew combination, where the nut is attached to the slide and the leadscrew is turned by a handle or handwheel at the back of the camera. With this set-up, the operator can stay in one position for focusing irrespective of the position of the lens panel on the slide.

On some hand cameras where the focusing scale extends only from infinity down to 3 or 4 feet, the lens panel is moved by a lever pivoted on the baseboard. The operating arm of the lever is relatively long and moves over a calibrated focusing scale. In this way it is possible to have an open and easily read scale even though the movement of the lens is no more than a small fraction of an inch.

Focusing Lens Mount. Where the amount of focusing movement required is no more than an inch or so and on all cameras where there is no separate lens panel (such as on most miniatures and self-erecting cameras) the focusing lens mount is the most convenient arrangement.

The simplest focusing mount consists of two closely fitting sections of tube sliding one inside the other, one holding the lens, and the other being flanged to attach to the front panel. This type of simple mount is good enough for visual focusing, but the backwards and forwards movement is too small to allow for accurate calibration.

But if a helical groove is cut in one tube and

FOCUSING MOVEMENT. Left: *A rack-and-pinion movement racks the lens panel forward and backward.* Right: *An alternative system moves this panel by a pivoted focusing lever.*

HELICAL FOCUSING MOUNT. The lens unit moves forward as a whole in a screw mount running in a similar thread in the camera body. Easy to couple to rangefinders. Left: *Infinity position.* Right: *Focused on near distance.*

made to engage with a pin in the other, a large rotary movement of the lens can be made to produce a relatively small forward shift. This is the principle of the helical focusing mount which is widely used in one form or another.

The helical focusing mounts on modern cameras may have either three helical grooves, or the groove and pin arrangement may be replaced by the more accurate, but more expensive, multiple-start screw-thread.

As the rotary movement of the helical screw is so much greater than the forward shift, it is possible to mark off a very accurate scale around the edge of the mount—the shift from infinity down to 3 feet generally covering about three parts of a full turn.

A pure rotary movement of a helical screw mount also rotates the lens with it—an inconvenient feature from the point of view of reading aperture scales, fitting rectangular lens hoods, etc. Most modern helical focusing mounts therefore incorporate a rectilinear movement which rotates only the mount but not the lens. The latter moves directly in and out.

Close-up Focusing Mounts. With cameras of normal dimensions it is difficult to design a helical focusing mount with a single screwed lens barrel that will focus the lens from infinity to closer than 3 feet (1 m.). This is a matter of geometry. However, some manufacturers—particularly in the 35 mm. and sub-miniature fields—have got over this difficulty by using two concentric threaded tubes interconnected with the focusing ring or arm in such a way that the outer tube unscrews fully before the inner one can start turning. When the focusing ring is turned back, the inner tube screws in first and the outer one next. The extra extension provided in this way allows a 35 mm. camera with a 5 cm. lens to be focused down to as close as 4 in. (10 cm.). This type of mount is more suited to miniature reflex cameras than to cameras with a separate viewfinder because it becomes impossible to compensate for parallax and difficult to focus by measurement at such close quarters.

Front Element Focusing. Many hand cameras—particularly the less expensive types—employ front element focusing in which the focal length of the lens is altered instead of its distance from the sensitive surface. This is done by moving the front element of the lens forward, and for this purpose the lens mount is split and the front element is set in a helical mount. As the front element of the lens is rotated, the separation between the lens elements increases, and the focal length shortens. The back element of the lens does not move, but as the lens now has a shorter focal length, it is now in front of its infinity position—i.e., it is focused on a closer distance.

The focusing scale is engraved around the rim of the lens, where a relatively large amount of rotation corresponds to a small shift of focus.

Although front element focusing is cheap and convenient, it is not by any means ideal. Its greatest drawback is its effect on the aberrations of the lens. These cannot be highly corrected over the whole range of lens element separations and an average value of correction which is always something below the best must be accepted.

Front element focusing complicates the use of such things as rectangular lens hoods, graduated filters and polarizing filters.

Focusing Back. It is not always necessary or desirable to focus a lens by moving it backwards or forwards. Alternatively, the sensitized material itself may be moved closer or farther from the lens to obtain the correct focus. This arrangement is made possible on some cameras by means of a focusing back—

FRONT CELL FOCUSING MOUNT. The rear components of the lens are fixed, but the front cell screws in and out, varying the separation between the elements and thus the focal length. Left: *Infinity position.* Right: *Close-up position.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

that is, the back of the camera can be moved to alter the lens-to-emulsion distance. This is effected by a normal rack and pinion mechanism; the rack used for focusing the lens normally is commonly made long enough to serve the back mechanism as well.

The principal advantage of the focusing back is that the image size on the focusing screen does not undergo great changes of size when brought in and out of focus—as occurs when focusing the lens itself. This is of importance when setting-up the camera to reproduce a particular image size: the camera distance is adjusted until the image on the screen is the required size and can be then focused with the back without upsetting the image size very much.

Most field and technical cameras are fitted with a focusing back.

The Focusing Scale. There is no standard system for calibrating focusing scales. One very good reason for this is that the number of divisions of the scale that are necessary between infinity and the closest focusing distance varies according to the focal length of the lens.

At the same aperture, a lens of 50 mm. focal length has twice the depth of field of a lens of 100 mm. focal length, so that it needs only half the number of subdivisions of its focusing scale for the same accuracy in focusing.

Very short focus lenses can, in fact, dispense with a focusing scale altogether. Instead, they can be focused quite satisfactorily in zones. The whole focusing scale is split into two or three zones, classified as near and distant, or near, midway and distant, and generally marked on the scale with coloured spots.

Long focus lenses, on the other hand, cover a relatively narrow depth of field and call for a focusing scale calibrated in short steps up to distances of several hundreds of feet in order to be sufficiently accurate.

Calibration. Where the focusing scale of a camera has been damaged or lost, it is a fairly simple matter to calibrate a substitute, especially where the focusing adjustment has an infinity stop—as it usually has. (If there is no stop, the infinity position can be found by putting a piece of ground glass in place of the plate or film, and focusing visually on a distant row of trees or buildings.)

The distance (d) that a lens of focal length (f) must be moved forward from the infinity position to focus sharply on any object at distance (u), is given by the formula:

$$d = \frac{f^2}{u - f}$$

If f is in inches, d and u must also be in inches.

Depth of Field Scale. Many cameras, in addition to a focusing scale, carry an indicator that shows the near and far limits of the depth of field of the lens at any particular aperture. The depth is often shown on the half of the focusing scale carrying the reference arrow. On each side of the arrow are scales corresponding to the lens aperture numbers. The positions of the pairs of aperture numbers indicate the limits of the depth of field on the adjacent focusing scale. For example, with a 90 mm. lens, focused on 10 feet, the upper scale would show *f* 8 on the depth scale opposite 8 feet on the focusing scale, and on the lower scale (on the other side of the focusing reference arrow) *f* 8 on the depth scale would appear opposite 12 feet on the focusing scale. This system of marking shows at a glance that when the lens is focused on 10 feet and stopped down to *f* 8 the depth of field extends from 8 feet to 12 feet. The depths at other apertures are shown in the same way opposite the relevant aperture values.

Where the depth of field is not shown directly on the lens mount in this way, it is often given in the form of a table engraved on a metal plate and attached to the side or back of the camera body. F.P.

See also: *Camera movements; Focusing.*

FOCUSING SCALE. Scale of distances marked on the focusing mechanism of a camera. When a particular distance is opposite the scale reference arrow, the camera lens is focused sharply on all objects at that distance.

FOCUSING SCREEN. Sheet of ground glass mounted in a frame and fixed in the camera in such a position that the camera lens forms a visible image on its ground surface.

In the normal types of screen-focusing cameras, the screen can be slid or swung away to allow the sensitive material to take its place. In the reflex camera the screen is fixed in the top of the camera and the rays of light passing through the lens are reflected on to it by a hinged mirror.

In each case the ground surface of the screen lies at exactly the same distance from the lens (measured along the optical axis) as the surface of the sensitized material. So that when the image is focused on the screen, an identical image will be formed on the surface of the sensitized material.

The clarity of the image on the screen is greatly affected by the texture of the ground surface. A coarsely ground screen gives a bright and well-distributed image, but it does not permit really fine focusing because the definition is limited by the granularity of the screen. A finely ground screen will give critical definition, but the illumination tends more and more to be confined to a small area of the screen lying on a line from the observer's eye to the back of the lens.

To counteract the drop in image brightness

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

from the centre to the edges of a focusing screen, a field lens is often used. This is a very thin Fresnel lens which evenly distributes the screen brightness.

In place of ground glass, some modern screens have a specially grained texture—often impressed in a plastic sheet. A combination of this with the Fresnel field lens principle has been used in some cameras to produce a particularly fine and evenly brilliant screen image.

Focusing screens often have pencilled grid lines to aid composition.

See also: *Focusing.*

FOCUSING STAGE. Accessory for miniature cameras and other models with interchangeable lenses (except reflex cameras) to permit accurate focusing on a ground glass screen when taking close-ups or photomicrographs.

Construction. The main parts of a focusing stage are:

(1) A ground glass screen housing, usually with a focusing magnifier.

(2) A camera holder.

(3) Provision for holding the lens, usually with a focusing mount incorporated.

(4) Provision for moving the ground glass screen housing and the camera body alternately into position behind the camera lens.

Focusing stages are always designed for specific cameras, but the principle is the same in each case. The ground glass screen housing is mounted on a movable platform together with the camera (without its lens). The housing is accurately matched to the camera, so that the distance from the subject to the ground glass screen is exactly the same as the distance from the subject to the focal plane of the camera.

The focusing magnifier may be a vertical or an inclined or right-angle one. Vertical magnifiers yield an upright but laterally reversed image; inclined and right-angle magnifiers incorporate a mirror or prism reflecting system above the ground glass screen and form an upright image which may be laterally reversed or right-way-round. Since focusing stages are mostly used for copying, the orientation of the image is not vitally important and the viewing direction is largely a matter of convenience with the particular set-up. In most cases the magnifiers are interchangeable.

For normal work, the power of the magnifier is about 4–5× but for fine focusing, high power magnifiers (up to 30×) are available.

The camera holder keeps the camera firmly fixed and accurately aligned alongside the focusing screen on the movable platform.

The movable platform permits either the camera or the focusing screen to be brought into position over the lens. The movement may be sliding or rotary. Instruments of the latter type are often called focusing turrets. Some types of focusing stage dispense with the movable platform altogether; the ground glass screen housing or the camera is simply screwed or clamped in position on the lens housing.

Using the Focusing Stage. The focusing stage is generally set up so that the camera points vertically downwards, though it may equally well be used horizontally. Camera and lens are fitted in position; the ground glass focusing screen is normally a part of the stage. With the ground glass screen housing in position behind the camera lens, the image is focused on the screen. The camera body is now moved over to replace the screen housing behind the lens. This usually requires a simple movement of the sliding or rotating platform. The exposure is then made by releasing the camera shutter in the normal way.

Owing to the unavoidable separation between the lens flange and the camera, the lens cannot normally be focused on infinity. Special ways of mounting the lens—e.g., by fitting a short barrel to a lens of long focal length—are adopted to overcome this limitation.

Focusing stages are more often used for close-up photography and copying, where the extra extension (about ½ in.) is necessary anyway. Additional extension tubes or bellows extension units are employed to obtain larger scales of reproduction. Focusing is carried out with the normal focusing barrel of the lens, or a special focusing mount between the lens and the stage.

The focusing stage is often the basis of a more extensive copying outfit incorporating an easel, support pillar, and lighting system.

By coupling the focusing stage to the tube of a microscope with an adapter, it can be used for photomicrography. When the stage forms part of a camera system, a suitable adapter is generally listed as an optional fitting. Usually a clear glass "aerial" focusing screen is also available. L.A.M.

FOCUSING STAGE. A sliding platform carries the camera together with a ground-glass screen housing. After focusing on the screen the camera moves into place behind the lens.

FOCUSING TURRET. Form of focusing stage, with the ground glass screen holder and the camera mounted on a rotating, instead of a sliding platform.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

FOG (ATMOSPHERIC). Mist is composed entirely of water-vapour particles and occurs in both town and country; fog is mist plus smoke (or more rarely, fine dust), so it occurs almost always in densely populated and industrial areas. The smoke particles are dark brown or black, therefore they tend to absorb all the light that falls on them. Under these circumstances, even deep filters make little improvement to the clarity of the picture since even the red and infra-red rays are absorbed.

Photography in fog, as in mist, is a matter of broad effects. In fog, however, the lights of street lamps, torches, vehicles and shops, offer possibilities which are often exploited for pictorial effects.

Exposure. There are no very definite rules for exposure in fog. So much depends upon the kind of result aimed at, the nature of the subject and its distance from the camera.

The exposure is not critical; a very wide range of values will give acceptable results. In general, exposures tend to be lengthy and it is advisable to use a fast panchromatic film.

Technique. To derive the greatest pictorial benefit from fog and mist, the following technique is advised.

Keep one object, preferably dark-toned, in the immediate foreground of the picture, as this helps to accentuate recession of planes and adds a "stepping-stone" for the eye into the picture beyond. An archway, statue, column, tree, etc., is suitable for this. If the fog is insufficiently dense to divide near-at-hand planes, use a diffusion disc on the lens. No exposure increase is needed. Should the subsequent print still exhibit too much definition and clarity, reprint, using the diffusion disc on the enlarging lens. Contrasts are flattened by this treatment, and paper one grade harder is required to counter the lack of dark tones.

The sun, in trying to break through, gives heightened effect on moist roof-tops and masonry. A viewpoint which gives oblique back-lighting is recommended. This produces unusual colour pictures too.

Photographing lighted street lamps, shop-windows, etc., in colour in fog during the day is mixing light of different colour-temperatures; however, it comes off very well in many instances.

Since visibility is limited, subject-interest should not be farther than 30–50 feet away from the camera, according to density and lighting. Use of flash, unless much nearer the object than the camera, has little to commend it. A strong beam of light, as from car headlamps, can give dramatic spotlight if falling at a suitable angle on to a person, obelisk, building, etc.

Limitations. Contact prints cannot do justice to pictures taken in fog and mist; consequently such negatives must always be enlarged. One or two in an album or collection are attractive and "different", more are apt to depress and defeat their own purpose.

It is best to, if possible, have a definite location and subject in mind before venturing with a camera in the fog—two or three hours wandering is conducive to chills and colds. Remember that mist and fog are damp, and prolonged exposure to them will mean that the camera has to be dried afterwards. P.J.

See also: *Mist.*

FOGGING. Fog or veil is any visible deposit or density in the negative or print not forming part of the photographic image. Several kinds of fog can be distinguished.

(1) Optical fog, caused by the action of unwanted light.

(2) Development fog caused by excessive silver deposit during processing.

(3) Chemical fog caused by unwanted reactions in the processing solutions (e.g., aerial fog).

Optical Fog. Unwanted light may reach the sensitive material:

(1) During loading or unloading the camera.
(2) In the camera itself.
(3) During handling in the darkroom.
(4) Due to unsafe darkroom illumination.

(1) Fog can be caused during loading and unloading of roll films if the spool is allowed to unroll itself partly after being unsealed or before being sealed up. The light then penetrates round the edges of the film and gives rise to patches of density extending from the edge and getting lighter towards the middle of the film.

Loading or unloading a film in brilliant sunshine carries a similar risk; this may also show itself on the first few frames of a 35 mm. film if the cassette opening is not absolutely light-tight—e.g., because the velvet is worn.

Plate holders may similarly develop light leaks, especially through a faulty velvet light-trap. These produce thin streaks of fog across the negative, heaviest near the end where the dark slide is withdrawn.

To avoid fog from these causes, roll films should be loaded and unloaded carefully in subdued light or in the shade; 35 mm. cassettes should not be reloaded indefinitely (except special types designed for the purpose); and plate holders should be examined periodically for leaks and have the velvet brushed or renewed if necessary.

(2) Light leaks in the camera itself produce irregular fog patches on the negative. The shape and position of these patches will usually give some clue to the location of the light leak.

The most common leaks occur in the bellows of folding cameras, but may also be traced to badly mounted lenses, or to an unsafe film window or to damage to the camera.

Scattered light and flare inside the lens also produce fog. This may be a thin general fog, or it may form patterns and patches due to reflections inside the lens when photographing

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

against the light. Both types are greatly reduced with coated lenses.

A dirty lens also scatters light.

All these types of fog (except those arising from leaks in the camera back) are characterized by the fact that they extend only to the limits of the image frame, but not into the margins of the film or plate which are normally clear.

(3) Stray light due to leaks, flare, and scattering can reach the paper on the enlarger baseboard during enlarging. This is analogous to stray light in the camera, and can be prevented by seeing that the enlarger lamphouse is light-tight, by avoiding bright reflecting surfaces on or near the enlarger, by masking the negative in the negative carrier to the actual area required, and by using a coated enlarging lens.

(4) Unsafe darkroom illumination due either to use of a safelight which is too bright or of the wrong colour: too long exposure of the material to it will produce over-all fog or uneven patches. Generally materials are more likely to be fogged before processing than after they have been in the developer for some time.

Fog of this nature is avoided by using the correct type and strength of safelight and keeping the material at the recommended distance from it. Panchromatic films and plates which are to be developed by inspection are best desensitized first.

Unsafe darkroom lighting also gives rise to several peculiar fog phenomena, such as the Sabatier effect and partial reversal of the image, while an unsafe red safelight may even destroy part of the latent image.

Development Fog. Development fog is the result of the development of unexposed silver halide grains. A special kind of development is also caused by the deposition of silver from the developer.

All emulsions contain a certain proportion of silver halide grains which are reduced to silver without exposure to light. This is the basic fog density and depends on the nature of the emulsion (e.g., high-speed panchromatic films usually have a higher basic fog density than slow process plates). It can, however, be influenced by storage conditions, by the activity of the developer, and by the use of restrainers or developer improvers.

Unsuitable storage increases the number of developable but unexposed silver halide crystals—often unevenly—and causes local or general fog.

Overactive developer, protracted development (including development to finality), and too warm a developer reduce a proportion of the unexposed silver halide crystals and usually give rise to general fog.

Potassium bromide reduces the activity of the developer and inhibits the development of unexposed salts. Developer improvers have a similar effect and will often also counteract the tendency of stale materials to become fogged.

Certain fine grain developers, particularly those incorporating a silver solvent, deposit silver on the image from the solution. A certain amount of this silver also tends to be deposited all over the film or plate as a general fog.

Chemical Fog. This covers all types of fog caused by side reactions in the developer and fixer. Two general groups can be distinguished (both may occur together):

(1) Silver deposits.

(2) Chemical stains.

(1) Silver deposits may be grey or coloured, depending on the fineness of the deposit. One well-known form is dichroic fog, which appears reddish by transmitted light and bluish green by reflected light. The main causes are:

Silver deposition from the developer: this is similar to the silver deposited by solvent developers, but it is more uneven and may be caused by contamination of the developer by fixing salts.

Silver deposition from the fixer: this may be the result of an excessive concentration of silver salts in an exhausted fixer. Alternatively, if the fixer is not sufficiently acid (because large amounts of developer have been carried over into it) parts of the image will go on developing in the fixer and produce solvent fog.

To prevent this type of fog, the fixer must not be overworked and special care should be taken to avoid contamination of the developer by fixing chemicals. A good rinse between development and fixing will prevent contamination of the fixing solution by developer.

(2) Chemical stains can also form in the developer or fixer. The commonest cause is aerial oxidation of the developer, from too much exposure to air during development. The oxidation products of certain developing agents (notably hydroquinone, pyro, and pyrocatechin) are strongly coloured and have marked staining properties. Such stains are particularly disturbing with prints, as the paper base easily takes and shows the stain. A general stain in a negative is less troublesome; in fact some developers (e.g., pyro-metol) are designed purposely to produce such a stain to improve printing quality.

Usually, however, such stains are not popular on negatives since they make estimation of printing exposures difficult. Also, stains of this nature are frequently uneven, and will thus show up in the form of patches on the print.

To avoid aerial oxidation, the material must not be exposed too much to the air during development, and prints must not be over-developed (certain contact papers are specially sensitive in this respect). Developers with too low a sulphite content have the greatest tendency to produce stains.

Aerial oxidation can also occur in the fixing bath if it is not sufficiently acid—e.g., because of carried-over developer. A stop-bath between development and fixing (with prints an acid

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

stop-bath) helps to prevent this fog from forming.

Too warm or too exhausted a fixing bath, especially one of the acid-hardening type, may produce uneven fog by toning parts of the image brown. This reaction is similar to that of the hypo-alum toner.

With colour films and colour prints, incorrect processing (wrong developer, wrong temperature, etc.), can produce both silver deposits and colour fogging—often noticed as a colour cast in highlights.

Removal of Fog. Uniform fog, provided it is not too strong, is not usually troublesome in negatives. If it is due to silver deposits, it can generally be removed by a weak reducer. For prints, a thiocarbamide reducer can be used; for negatives, Farmer's reducer is usually most convenient.

Chemical fog caused by oxidation will often disappear if the image is bleached in a permanganate bleacher and redeveloped in a non-staining developer (but not a fine-grain formula).

Restoring Unused Fogged Materials. Any plates, films and bromide paper that have been accidentally exposed to light may be made usable by soaking for five minutes in either of the following solutions.

Chromic acid	110 grains	6·2 grams
Potassium bromide	220 grains	12·5 grams
Water to	40 ounces	1,000 c.cm.
Potassium bichromate	160 grains	8·3 grams
Hydrochloric acid	1 ounce	25 c.cm.
Water to	40 ounces	1,000 c.cm.

The treatment should be followed by thorough washing and drying and the whole process must be carried out in darkness. The speed of the material should be rated at 1/5 to 1/10 of the original figure. L.A.M.

See also: *Faults; Keeping qualities of materials.*

FOG LEVEL. Basic density of fog produced by development of a sensitized material without exposure. The minimum density of the photographic image produced by exposure must be sufficiently above the fog level to show detail. Paper prints should have no fog level at all, or the highlights will appear degraded.

See also: *Fogging; Speed of sensitized materials.*

FOLDING CAMERA

All the early cameras had to fold because they used such large plates that a rigid body would have presented serious problems in transport and storage. But today the term is restricted by usage to cameras of the quarter-plate ($3\frac{1}{4} \times 4\frac{1}{4}$ ins.) or smaller sizes.

Sizes. The majority of folding cameras in the popular class take size 120 or 620 roll film and yield 8 exposures $2\frac{1}{4} \times 3\frac{1}{4}$ ins. (6 × 9 cm.) or $2\frac{1}{4} \times 2\frac{1}{4}$ ins. (6 × 6 cm.). A number of models are also made for 16 exposures $1\frac{5}{8} \times 2\frac{1}{4}$ ins. (4·5 × 6 cm.) on the same size of film. Certain types will take two picture sizes, e.g., $2\frac{1}{4} \times 3\frac{1}{4}$ ins. and $2\frac{1}{4} \times 2\frac{1}{4}$ ins. or $2\frac{1}{4} \times 3\frac{1}{4}$ ins. and $1\frac{5}{8} \times 2\frac{1}{4}$ ins., by means of a thin metal mask inserted into the film aperture. Sometimes this mask is built in, and folds away into the film chambers.

The next most popular film is size 127 for 8 exposures $1\frac{5}{8} \times 2\frac{1}{2}$ ins. (4 × 6·5 cm.). Reduced picture sizes (e.g., 12 exposures $1\frac{5}{8} \times 1\frac{5}{8}$ ins. or 4 × 4 cm. and 16 exposures $1\frac{1}{8} \times 1\frac{5}{8}$ ins. or 3 × 4 cm.) are rarer but exist. Cameras taking other roll film sizes (e.g., 116, 616, 29, etc.) are virtually obsolete.

The folding camera is today mainly a thing of the past, and only very few models are made, although the folding press-type of cameras in the 4 × 5 ins., $\frac{1}{4}$ plate, and 6 × 9 cm. formats are still popular. The latter can be regarded as mainly professional equipment.

An appreciable number of precision folding cameras use 35 mm. miniature film. These are, however, miniature cameras in all respects and will not be considered here.

The simplest type of folding camera is simply a box camera designed to go into a smaller space. Each manufacturer added his own improvements to this basic type, but most of the major developments are common to all makes.

Construction. The classical folding camera is a shallow box, one side of which hinges outwards and can be locked at right angles to the body to form a baseboard. This baseboard supports the lens and shutter when open, and protects them when closed. A light tight bellows joins the lens panel to the body. The back of the body has either an attachment for plate holders and a focusing screen, or if it is a roll film camera, spool chambers, a pressure plate, film guide, and number windows. Some folding cameras are made to take both films and plates.

The lens panel can be moved to and fro to focus the lens. Focusing is generally from 3 feet to infinity, but on double and triple extension types the baseboard telescopes out to give increased extension for close-up photographs.

Most folding cameras for popular use have a self-erecting lens mounting that springs into position automatically when the baseboard is released. Once in position the lens is focused either by rotating it in a helical focusing mount, or moving it bodily by a lever acting on the self-erecting mechanism. Sometimes there is no hinged baseboard and the lens panel simply springs forward into position on a lazy-tongs device.

Folding cameras for technical or close-up work, however, still retain the baseboard and

Usually covered with a safety shutter.*

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

guide rails because it is not possible to incorporate the necessary double extension and rising and cross front in a self-erecting lens panel.

Optical Equipment. Normal folding roll film cameras are fitted with 3- or 4-element lenses of triplet construction and maximum apertures from *f* 6·3 (*f* 8 or 11 in simplest models) to *f* 3·5 or *f* 2·8. Certain precision cameras of this type may also feature more advanced 5-element lens systems.

Normally the lens is not interchangeable (folding, press and field cameras are exceptions), but the standard models of most makes are available with a choice of lenses and shutters to suit different price levels.

Many folding cameras in the expensive class have a built-in rangefinder coupled to the lens through the self-erecting mechanism. Adjustment of the image of a particular object in the rangefinder automatically focuses the lens on that object.

The rangefinder is adjusted by a lever or knob on the camera body.

On a number of models, a rangefinder is built in but not coupled to the lens. Measurement of distance and focusing involves two operations in such a case.

The better folding cameras almost always have direct-vision optical viewfinders.

Some cameras with coupled rangefinder focusing use the same window for rangefinder and viewfinder. In this way no time is wasted in shifting and refocusing the eye between adjusting the rangefinder and taking the photograph.

Shutter Equipment. Amateur folding cameras almost invariably carry a between-lens diaphragm shutter. The simplest versions have 2- or 3-speed types with X-synchronization, advanced models feature 4-speed to 10-speed shutters with maximum speeds up to 1/500 second and XM-synchronization.

On the earliest models the shutter release was always a part of the actual shutter mechanism. It was often a small projecting lever, difficult to locate, and by no means standardized in its method of operation. In more recent years the shutters of the better folding cameras were released by pressure on a substantial button or plunger on the body of the camera.

Film Transport. The film is wound on by a knob or key, usually directly connected to the shaft which engages the film take-up spool. On more modern cameras a film lock automatically arrests the transport mechanism when the right amount of film has been wound on, and also works a mechanical film counter. On most models, however, a red window in the camera back serves for observation of the numbers on the backing paper to determine the correct position of the film from one exposure to the next.

The risk of making a double exposure is avoided by mechanically coupling the shutter release and film winding mechanism so that the shutter cannot be released for a new exposure until the film has been wound on to the next frame. Such coupling is not a simple matter and it is found only on the more expensive folding cameras.

Scope. The convenience of the folding camera has been exploited in practically every field of photography. It has a close rival in the miniature camera which is equally adaptable. There is very little to choose between the actual bulk of the two cameras. The most powerful argument in favour of the miniature camera is the increased versatility of the expensive precision models with their wide range of special accessories. The larger folding camera can advance the argument that it takes a bigger picture and is less troubled by dust, scratches, grain in the film, and inevitable deterioration in the quality of the image when greatly enlarged. F.P.

FOOD. There is a steady demand from advertising agents and the cookery page editors of women's magazines for photographs of prepared dishes. Such photography may look easy but it is beset by as many difficulties as any other specialized branch of illustration.

Sensitized Material. While there are still examples of the use of black-and-white material for photographing food, the majority of such pictures are now taken in colour because the colours of an expertly cooked dish and of the garnishes, sauces, table linen and decorations provide much of their attraction.

The need for first class definition in the final reproduction rules out 35 mm. colour which tends to lose some sharpness in enlargement and reproduction.

Most workers in this field use an integral tripack cut film which they process in the studio darkroom.

Camera. Specialists almost invariably use a professional plate or sheet-film camera, and a negative size which may vary from ¼ plate to 10 × 8 ins. The negative material used today is mainly of the sheet-film type. Anything smaller than ¼ plate, is likely to involve a loss of quality intolerable for this type of work.

This work calls for a selection of lenses of varying focal lengths since the subject may be a single dish or a laid table. Large apertures are not important since there is no objection to moderately long exposures. But all lenses must be fully colour corrected and capable of giving critical sharpness right to the picture edges.

Lighting. Artificial lighting is always used because it is always under control and it allows conditions to be reproduced exactly if a retake is necessary. Normal lighting equipment is suitable provided that all the light sources are of the same colour temperature and adjusted

to the colour material in use, by filters if necessary. Fairly powerful sources are used to keep the exposure down to reasonable limits, but none of the lamps must be close or powerful enough to dry up the food during focusing and exposure.

CC-0. Agamnidam Digital Preservation Foundation, Thiruvananthapuram

Preparing the Photograph. Food pictures which accompany "How-to-do-it" magazine articles or advertisement copy must be true to colour and sharp all over since the photograph must give an exact impression of the subject.

A good food picture is the result of careful planning and team work between photographic and culinary experts. The food must be both perfectly cooked and perfectly displayed if it is to appeal to the magazine reader.

As a rule, the photographer has little freedom to choose the picture; he works to a scheme decided upon after long and often tedious editorial conferences. And as most periodicals are planned several months ahead, he may have to provide special delicacies which are out of season together with suitable floral decorations. Fortunately such things are easier to obtain nowadays thanks to deep frozen food and flowers by air.

At the same time, the photographer learns by experience that certain foodstuffs do not photograph well and he must be able to suggest reasonable substitutes.

If the photographer is not himself an expert in the kitchen, he must work in conjunction with an experienced chef who can look after both the preparation and display of the food to be photographed.

The specialist food photographer works in a combined studio-kitchen or kitchen-studio, the main thing being to have the photographic apparatus on the spot where the food is being cooked. He must decide in advance on the correct style and arrangement of table linen, silver, china, flowers, etc. Close attention to such details is vital because the final picture must survive the critical inspection of expert housewives and cooks.

Taking the Picture. Once all the necessary preparations have been made, a rehearsal should first be staged with a dummy dish and a trial exposure actually run off to make sure that everything is as it should be. Retakes in this type of work can waste a great deal of time and money.

If the trial exposure is satisfactory, the picture is arranged and then, just before making the exposure, the real dish, freshly prepared, is slipped into position. In this way the food appears fresh and attractive; nothing looks worse than a meal that has been standing for some time. And under the powerful lighting normally used, the colour and general appearance of food can change very quickly.

The arrangements must be organized to run smoothly and without crises. Careful timing is called for; most dishes take some time to bring to the point when they are ready for serving, and a dried up vegetable or a cold, greasy-looking meat dish can ruin the picture, discourage the cook and put everyone concerned to the trouble of a retake.

H.G.C.

FOOT (FT.). Lineal measure equal to 12 ins. or 1/3 yard. The foot measure is common to all nations and periods being based on the length of the human foot from which it takes its name.

See also: *Weights and measures.*

FOOT CANDLE. Unit of illumination representing the light intensity over a surface one foot away from a standard candle. It is equal to one lumen per square foot.

See also: *Light units.*

FOOT LAMBERT. Unit of luminance representing the brightness of a perfectly reflecting and diffusing surface when the light falling on it has an intensity of one foot candle. Also known as an effective foot candle.

By international agreement luminance is now expressed as luminous intensity per unit area, e.g., in candles per square metre or square foot.

See also: *Light units.*

FOOTAGE COUNTER. Measuring device in a cine camera to show the length of film of a load already used up. Usually the mechanism is very simple and relies on measuring the thickness of the film wound up on the take-up spool, giving an approximate indication of the exposed length.

See also: *Cine camera.*

FORCEPS. Various types of forceps are used in photography for manipulating prints in the developer, stop bath, fixer, and other solutions to keep the fingers dry and prevent them from becoming contaminated with solution and spreading stains. Forceps also reduce the risk of contamination of the various solutions with each other, and save a great deal of the time taken up by rinsing the hands or fingers before handling unexposed papers again.

Print forceps may be of various sizes (the largest are generally most practical) and are available in plastic or stainless steel.

One pair of forceps is required for the developer and another for stop bath and fixer, to avoid contamination. In practice the print is lifted from the developer with the developer forceps, dropped into the stop bath without immersing the forceps, and handled from then on with the fixing forceps.

To prevent accidental interchange, the two pairs of forceps should be different in size, type, or colour.

Plastic forceps are preferable for the fixer, since stainless steel collects a silver deposit

from the silver in the fixing bath and becomes discoloured in time. The silver can usually be removed by immersion in an ordinary negative reducer (e.g., permanganate), or by polishing with a silver polish.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

See also: *Print paddle.*

FOREGROUND. The part of the scene that lies nearest the camera. The great depth of field of a miniature camera makes it possible to include very near objects in the foreground and still render them sharp. With larger formats this may only be possible by stopping the lens right down and giving a very long exposure. If the camera is fitted with movements, the front can be swung to bring the foreground into sharp focus without stopping down the lens.

A blurred or out of focus foreground is generally unpleasing, but there are occasions when it helps to add depth to the picture by pushing the subject back into a more appropriate perspective. A similar effect can be achieved by the use of heavy, dark tones in the foreground to frame the more distant subject—e.g., by shooting from under an archway or through overhanging foliage.

See also: *Camera movements.*

FORENSIC PHOTOGRAPHY. Application of photography to the law, criminal investigation, police court proceedings and the like.

See also: *Crime photography; Evidence by photographs; Fingerprint photography; Forgeries; Police photography.*

FORESHORTENING. Appearance of an object when viewed obliquely. A relatively long and slender object—e.g., an arm or leg—when seen at an oblique angle by the camera gives an image which is by comparison short and thick. The size of near parts of the subject may appear greatly exaggerated if, in addition, the viewpoint is close.

See also: *Perspective.*

FORGERIES. Photography has made possible a number of techniques for detecting forgeries.

Forgery may be defined here as the fraudulent making or alteration of any document with intent to deceive or, as the old common-law definition runs, "to the prejudice of another man's right". "Documents" in this context may be widely construed to mean not only letters, receipts, cheques, wills, registers, business papers, certificates of ownership, passports, etc., but also paper money, books and even pictures.

Forgery can of course be a serious criminal offence; its detection and proof therefore call for careful expert examination of the questioned documents. Photographic methods constitute a generally useful and sometimes essential part of this examination.

We may distinguish between documents which are:

(1) Wholly false, or

(2) Partly genuine and partly false, where the forgery has consisted in making an erasure and/or alteration and/or addition to some material part.

In general, photography is of less importance in the examination of documents which are wholly false, in which the chemical and physical analysis of papers and inks is in most cases of relatively greater importance.

Technically speaking, the expert examination necessary may also be divided into:

(1) Handwriting comparisons, and

(2) All other types of examination.

The reason for this distinction is that the study of handwriting (including typewriting) to test genuiness or determine authorship is a very specialized expertise, acquired only by considerable experience and with only a limited number of practitioners, whereas the other types of examination depend much more on the application of techniques familiar to every competent forensic scientist.

The uses of photography in this field fall broadly into three categories.

(1) The permanent recording for the examiner, or illustration for a court, of visual findings made during the examination. This commonly requires photography at magnifications of, say, 1 to 20 times, sometimes with the aid of colour filters. Sometimes also colour photography is necessary for a proper display of the significant findings.

(2) The duplication of parts of documents as a stage in their comparison. This applies particularly to handwriting examinations. The expert's normal procedure there is to copy the questioned and control documents at rather over natural size (sometimes a direct photocopying process suffices), cut out and assemble all the examples occurring of each individual letter and stroke formation, and examine analytically whatever regularly recurring characteristics may be revealed by this process.

(3) The use of photography as a scientific tool in its own right for gaining information obtainable in no other way. This normally involves photography using an isolated region of the spectrum, possibly one outside the visible range. The following photographic techniques may all be used for these purposes.

Straight Macrophotography. Usually this is done in black-and-white or (less commonly) colour. Apart from its use in handwriting comparison already mentioned, this is used for the demonstration of "awkward" joins produced by additions and alterations. Magnified recording of stroke intersections can show the order of writing, as a wet ink stroke which crosses one already dry diffuses into the latter. (This does not apply to ball point.) In the comparison of genuine and forged paper money and certain official documents the forgery reveals itself partly by the fact that its printing lacks the clarity and crisp quality of that on the genuine document.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Specimens of handwriting and typewriting may also be compared by using simple transparencies. The complete identity of two signatures is a proof that one is forged and was copied from the other by tracing, since no one ever makes two completely identical signatures. The same process will reveal those small irregularities of alignment and spacing which characterize a particular typewriter.

Filters. The use of complementary and contrast filters in the visible region can: isolate material from a distracting background (cancellation marks on stamps or writing on a stained or closely printed surface; or render pale coloured writing as dark as possible; differentiate between two closely similar but not identical hues. As already mentioned, the most satisfactory result is sometimes obtainable only with colour photography.

Photography by Infra-red. The uses of this can be broadly divided into:

(*a*) utilization of the fact that infra-red penetrates paper better than visible light;

(*b*) utilization of the differing infra-red reflectivities of visually similar dyes and pigments.

The first may for example render incompletely erased pencil strokes legible, the incomplete erasure having left some graphite particles just under the surface of the paper. The second is perhaps the most useful single technique in distinguishing fraudulent alterations; even if these are so skilfully done as to be visually unnoticeable, the chances are that the inks of the original and added entries will have different infra-red reflectivities. In some cases, also, certain otherwise difficult colours (e.g. browns) can be filtered out using infra-red.

Ultra-violet Photography. "Straight" ultra-violet photography is not often utilized. It requires only a source of ultra-violet radiation (normally a mercury-in-quartz arc) and a filter transmitting ultra-violet only. All emulsions are highly sensitive to ultra-violet. Such photography is of course limited to the 360–400 mμ region when ordinary photographic lenses are used, since glass absorbs wavelengths less than about 360 mμ. However, even with this limitation, it can be useful for differentiating certain visually indistinguishable pigments.

The examination and photography of fluorescence (i.e., the re-emission of absorbed ultra-violet as visible radiation) is on the other hand much used in this field. It is particularly valuable for revealing ink writing which has faded or has been obliterated by chemical means. The fluorescence of the paper base is affected by the chemicals which have soaked into the paper from the ink.

Since fluorescence is always very faint compared with the exciting radiation, it is essential to illuminate the document with ultra-violet only (ultra-violet lamp with Wood's glass screen) and to let only visible light reach the emulsion by using an ultra-violet-absorbing filter on the camera. The exposures will be long, and panchromatic emulsions should be used as the fluorescence may be of any colour.

Shadowgraphy with X-rays. This could of course be considered not strictly a photographic process, since it does not require a camera or lens, and since whatever it reveals could in many cases have been seen on a fluorescent X-ray screen. However, photography on X-ray film is normally more convenient. This is a standard procedure in testing the authenticity of paintings, since it may reveal earlier brush-work which has been painted over.

An allied technique uses a slightly radioactive sheet material instead of X-rays—e.g., acrylic polymer sheet containing carbon-14. The radioactive sheet, the document and a piece of X-ray film are clamped together as a sandwich and a rather long exposure given (hours or days). This may be used to reveal the structure of paper and similar materials which are more or less opaque to light but completely transparent to normal X-rays. It has been used to detect philatelic frauds by showing up otherwise invisible gummed joints, etc. H.J.Wa.

Books: *Evidential Documents*, by J. V. P. Conway (Springfield, Illinois); *Suspect Documents, their Scientific Examination*, and *Forgery Detection*, both by Wilson R. Harrison (London); *Questioned Document Problems*, by Albert S. Osborn (Albany, New York).

FORMALIN. Formaldehyde solution. Used as a hardening and tanning agent, especially for scratch-proofing.

Characteristics: Colourless liquid with unpleasant pungent smell. Formalin is a 40 per cent solution of formaldehyde gas (HCHO, molecular weight 30) in water.

FORMAT. Size of a book with particular reference to the relative proportions of the lengths of the sides. The depth of the page is always stated first—e.g., the format of this book is $9\frac{1}{4} \times 6\frac{3}{4}$ ins. Also applied to photographs.

FORMULA. In photography the term applies to the recipe of ingredients required to make up a particular processing solution—e.g., a developer.

It also applies to the symbols indicating the molecular composition of a chemical—e.g., $AgNO_3$ (silver nitrate).

See also: *Chemical symbols; Solutions.*

FOUCAULT, JEAN BERNARD LÉON, 1819–68. French physicist. One of the foremost photographic scientists in the first quarter century of photography. Constructed (1844, with Donné) a projection microscope, and (1849, with Duboscq) an electric arc lamp. Studied (1844, with Fizeau) the effect of light on daguerreotype plates, and produced the first daguerreotype photograph of the sun in 1845. Collected works edited by Gabriel and Bertrand (Paris 1878).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

FOURIER ANALYSIS. Mathematical technique which can greatly simplify the analysis of complex waveforms, used in the evaluation of optical images and of recording systems. A waveform may be considered as the sum of its individual frequency components (sine and cosine waves), and the effects of any system by which it is transmitted or recorded may then be expressed at any frequency as a simple scale factor.

Book: *Fourier Methods in Optical Image Evaluation*, by H. E. Linfoot (London).

FOX TALBOT, WILLIAM HENRY, 1800–77. English archaeologist, chemist, linguist, mathematician and inventor of photography.

See also: *Talbot, William Henry Fox.*

FRAME. Single image in a series on a strip of film. Applied mainly to cinematography (for example in defining frame size and camera speed in frames per second), but also used in still photography where for instance a single exposure on a 35 mm. film is often referred to as a frame. As this frame size is normally 24 × 36 mm., an 18 × 24 mm. image size is often referred to as a half-frame.

The frame is also the boundary in the viewfinder which outlines the limits of the field-of-view of the camera. Framing a shot means aligning it within this viewfinder frame, so that the latter takes in just the subject field required.

FRAME COUNTER. Precision measuring mechanism built into certain more advanced cine cameras to show the actual number of individual frames exposed during the run of a film. It is used for accurate location of a particular spot on a film, when rewinding for double exposures, dissolves and other effects.

See also: *Cine camera.*

FRAMING PHOTOGRAPHS. There are two principal reasons for putting a photograph in a frame: so that it can be hung up easily and seen to better advantage, and to protect it from dust, damp and finger-marks while it is displayed.

The amateur, unless he is an experienced carpenter, is best advised not to attempt to make a frame. The result will almost certainly be a waste of time and timber.

A photograph that deserves a frame will usually justify the expense of having it professionally framed.

It is of course possible to buy frames ready-made. All the photographer has to do then is fix the photograph in the frame—not quite such a difficult task.

The actual designs of frames vary considerably. In its simplest form a frame can be made of quite plain wooden moulding; a more elaborate type may consist of a number of ornate borders of machine decoration. The modern trend however is to use a simple, narrow frame with plain sides.

Choosing the Frame. The frame should normally be plain and unobtrusive. Its purpose is to isolate the photograph from its surroundings so that the picture will attract and hold the attention. An ornate or showy frame only draws attention away from the picture or at least clashes with it.

If the photograph is to fill the whole space in the frame, the frame should be a wide one; otherwise the picture will not be sufficiently isolated. If the photograph is to appear on a mount, then the frame may be narrow, because in this case, the mount itself can provide a border. Generally, the bigger the mount in relation to the photograph, the narrower can be the frame.

The glass should be of the kind intended specially for framing pictures; this is much thinner than the glass used for glazing. The quality of this glass varies widely, so it should be carefully inspected for flaws and waviness. These faults show up much more over a black and white photograph than over a coloured painting.

It is a good plan to run a narrow strip of gummed paper around the edge of the glass and the inside of the frame before fitting the picture in position. This prevents dust and damp from entering from the glass side of the frame.

Framing the Photograph. Before starting the actual framing, the print should first be mounted. The mount must be fairly thick and fit the frame exactly. If a cut-out mount is used it must be backed with card of the same size. The glass in the frame must be cleaned thoroughly—especially on the inside surface. The mounted photograph is placed in the frame and secured along all edges with heavy gummed paper; this is stuck with half its width over the back of the mount and the remainder over the back of the frame.

Cord or wire for hanging the picture should be attached to the frame and not the mount. This is best done by fixing a screw eye into each side of the frame. The cord is attached to the eyes and kept short so that it does not show above the top edge of the frame (unless the picture is to hang from a picture rail). Normally it is better to hang it from a hook held by one of the special hard steel pins which can be driven into plaster or wood without leaving an ugly hole.

Passe-partout. A cheaper way of framing photographs is to use passe-partout binding.

For this type of framing it is essential for the print to be on a mount of least 1/16 in. thick.

A piece of picture glass must be cut to exactly the same size as the mount or the mount may be cut to match the size of the glass, using the glass as a template.

The mount and glass are then bound together

with the passe-partout tape. The latter can be used in one complete length or cut into four strips—one for each side. This second method is the easier, especially when dealing with large pictures. The passe-partout in either case must be mitred on the corners of the picture.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

In cases where it is ever likely to be necessary to remove the print from its frame or passe-partout binding, a backing card or board should be used. The backing is cut to the same size as the mount and fitted over it before applying the binding.

Stick-on hangers can be obtained for attaching the cord or wire to the back of the mount. These are surprisingly efficient although they may not look reliable. Another type has a ring on a split pin; the pin is pushed through the mount and secured by bending flat on the other side. If this system is used, obviously the mount must be backed with a second piece of cardboard; the split pin is then only pushed through the rear card. It is of course essential with this method to attach the ring before binding together the glass, mount and backing card.

Whether using a proper frame or passe-partout binding, some thought should be given to the colour. This should contrast with the wall on which it is to hang; if it blends into the wall its purpose (which is to isolate the picture) is defeated.

J.D.C.

FRANCE

Like all inventions, photography was the culminating result of patient work in many countries extending over a period of centuries. Nevertheless, it is certain that an image of the exterior world was permanently recorded on a light-sensitive surface for the first time in France.

Early Experiments. Nicéphore Niépce (1765–1833) was the first man to succeed in recording an image in a camera obscura. In May 1816 he photographed buildings on his property near Châlon-sur-Saône on sheets of paper impregnated with silver chloride, but was unable to fix them. He experimented with various materials such as paper, glass and metal (zinc and copper). In 1822 he obtained recognizable images on glass coated with bitumen of Judea, though not in a camera obscura.

Between 1823 and 1826 he improved the process, which he named heliography and in which the image was obtained on a bitumen coated plate of zinc or pewter. After exposure the unaffected bitumen layer was dissolved away. Copies of line drawings obtained by superimposition could be satisfactorily etched and used as printing plates. Camera views, however, were too faint to be transformed into printing plates. Niépce's first view from nature was taken from his window in 1826. The following year he submitted a communication on heliography together with specimens to the Royal Society, London, who could not give it recognition because he did not disclose manipulatory details. Niépce was also the first man to suggest the use of an iris diaphragm to correct lens aberrations and eliminate marginal rays.

While Niépce's final object was to make printing plates of camera pictures, L. J. M. Daguerre (1787–1851) aimed simply at camera pictures, and it was his meeting with Niépce that led to his success. In 1827 Daguerre made Niépce's acquaintance through the optician C. L. Chevalier and on the 14th December 1829 they went into partnership.

The Daguerreotype. Both during Niépce's lifetime and after his death the process was gradually improved, finally resulting in the daguerreotype: a copper plate was coated with silver iodide and the photographic image was developed by the action of mercury vapour and fixed by what is today known as sodium thiosulphate. On 7th January 1839 Arago announced the invention to the Académie des Sciences. The French government then voted legislation for the purchase of the process "in order to offer it as a free gift to the world", and on 19th August 1839 Arago repeated his announcement and described the invention at a formal session of the Institut de France.

The daguerreotype process had a number of disadvantages, the principal one being that only a single copy of each exposure could be obtained. In February 1839, Hippolyte Bayard (1801–87) invented a negative-positive paper process. However, his direct positive process on paper, invented the following month, was much better. Unfortunately, it did not win commercial success and Bayard's name was forgotten for many years.

Later Developments. W. H. Fox Talbot's process was an improvement on the daguerreotype; it was perfected in France by Louis Blanquart-Evrard in 1846 and Gustave Le Gray in 1849. The latter obtained excellent transparent negatives by the use of dry waxed paper.

In 1851 Blanquart-Evrard opened an "imprimerie photographique" (photographic printing works). He made large numbers of photographic prints which were published in albums, thus being one of the very first workers to undertake systematic mechanization of the photographic process.

In 1847, Claude Niepce de Saint Victor (1805–70), a cousin of Nicéphore Niépce, invented the albumen process. The sensitized surface consisted of silver nitrate, the developer was gallic acid and the fixer sodium thiosulphate.

In 1849, Le Gray suggested the possibility of using collodion in photography—a solution of

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

gun cotton in ether, but the process was first invented by Frederick Scott Archer who published it in 1851. During the siege of Paris in 1870 the collodion process was used to make microfilms for sending messages across the enemy lines by carrier pigeon.

At this period numerous French experimenters developed various mechanical processes for the reproduction of photographs, e.g., Hippolyte Fizeau (1841)—Niépce de Saint Victor (1853) and Alphonse Poitevin (1855). In 1878, Petit invented a system of producing dots for the half-tone process. About 1858 Nadar succeeded in making instantaneous exposures by the light of a Bunsen battery.

Colour Photography. The next major invention after Niépce's to which Frenchmen can lay claim is that of colour photography. In his communication of February 1891 to the Académie des Sciences (Academy of Sciences) Gabriel Lippmann (1845–1921) explained the principles of the interference method.

But colour photography had been invented already in 1869 by two men working independently: Charles Cros (1842–88) and Louis Ducos du Hauron (1837–1920). In February of that year these two experimenters announced the principles of three-colour photography. They produced the first colour images by the superimposition of three plates.

In 1907 the brothers Auguste and Louis Lumière produced their autochrome plate, using a pigment process which made additive colour photography a commercial proposition.

Applications of Photography. France has made an important contribution to the study of movement by photography, which led ultimately to the motion picture. E. J. Marey (1830–1904) made a "fusil photographique" (photographic gun) in 1882. In 1883 he founded in Paris a centre for studying movement, and this still exists today under the name Institut Marey. In 1888 he perfected his process by making a "chronophotographe à pellicule" (film chronophotograph).

Finally on the 13th February 1895 the brothers Lumière announced their invention of the process which they christened "cinematograph".

Experiments in stereoscopy began very early, as is shown by the fact that daguerreotype pairs are in existence for stereo viewing. In 1891 Ducos du Hauron had perfected the anaglyph method of stereo viewing.

In connexion with the scientific applications of photography the following names deserve mention:

In 1861, Colonel Aimé Laussedat invented the process of photogrammetry, enabling linear measurements to be taken over great distances by photographic means.

In 1919, Poivilliers invented the stereotopograph, an apparatus working on stereoscopic principles for the measurement of heights from aerial photographs.

The history of photomicrography goes back to 1840. In that year Dr. Alfred Donné produced daguerreotypes with a microscope, and in 1845 he published the first book illustrated by photomicrographs.

In 1882 the brothers Paul and Prosper Henry made an important contribution to astronomical photography by devising a photographic method of recording the transit of Venus from the Pic du Midi observatory. As a result, an international union was formed for mapping the skies.

In the same year, Alphonse Bertillon took out a patent for a system of photographic identification, which is still in use in most countries of the world for criminal record purposes.

In 1908 Edouard Belin invented a method of transmitting pictures by wire. In 1914 the first news photograph to be transmitted by "belinogramme" was published. It is now in regular use in newspaper offices.

The Art of Photography. In its early days, photography was mainly used for portraiture. Most daguerreotypes were portraits. Some remarkable views of Paris were made by this process between 1840 and 1850, many of them by Bayard.

Gustave Le Gray and Blanquart-Evrard later made a number of landscapes and views of monuments. But the long exposure time required made the taking of action pictures difficult. Maxime Du Camp travelled in Egypt, Nubia, Palestine and Syria between 1849 and 1851 and brought back some remarkable "photographic drawings", as he called them.

Many amateurs took up photography as a hobby; amongst them Victor Hugo, his sons and his son-in-law Auguste Vacquerie made a fine collection of pictures in Jersey and Guernsey from 1853 to 1870.

Photography made its official public début in a section of the World Exhibition of 1855 in Paris.

During the whole of this period photographers concentrated on a realistic portrayal of their subjects, and the results, particularly in the case of Bayard's work, were generally not lacking in charm. Portraits were very conventional and, in general style resembled the work of contemporary painters. The outstanding pioneers were the Nadar family, foremost among them Felix Tournachon, called Nadar (1820–1910). Together with his brother he opened a studio in 1852 which was later taken over by his son Paul. Nadar was a curious type, a man-about-town, inventor and friend of Jules Verne; he went in for ballooning and all sorts of other adventurous experiments besides his photographic activities. His portraits, which depict the celebrities of a whole period of history, have a very distinctive and vigorous style and they gave rise to much controversy on the question of whether photography could be called an art, in the course of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

which Charles Baudelaire took his stand against photography while Eugène Delacroix was in favour of it.

Under the Second Empire (1852–70) another photographer, André Disderi, achieved great success with multiple portrait photographs in small format, which became known under the name "Carte de Visite". So popular did these become that as Napoleon III was riding through Paris at the head of his troops on the way to the war in Italy in 1859, he did not hesitate to stop the procession in order to have his portrait taken by the "Master" as a memento of the great occasion. At the end of the Crimean war (1855) photographic history was made when a photograph was taken instantaneously at the victory parade in Paris.

In the same period, two Parisian workers are worthy of special mention: the portrait photographer Adam Salomon and the landscape photographer Adolphe Braun; the latter also took excellent studies of contemporary Parisian life.

Later, serious photography, like original art, underwent an eclipse for a number of years, though it did become a popular pursuit among amateurs. Paul Nadar made some excellent portraits of important personalities; particularly worthy of mention are the serial studies in expression of General Boulanger and the chemist Michel Chevreul, which were published in the newspaper *Le Figaro* in 1886/7. But photographs as a whole became a bad imitation of the worst painting.

Puyo and Robert Demachy made some good pictorial studies with soft-focus effects. At the turn of the century a swarm of photographic clubs encouraged the spread of this rather over-rated technique.

One photographer was in a class by himself and a forerunner of the modern school: his name was Eugène Atget (1856–1927). Though he enjoyed no commercial success, he produced straight photographs without any special effects. Apart from their considerable documentary value, Atget's photographs still seem very fine today and have a certain naïve charm.

After the end of the first World War the most prominent French photographers were Madame Laure Albin-Guillot and Emmanuel Sougez. The latter is particularly noteworthy for having introduced the conception of pure photography into France. His work, the best of which probably consists of still life studies, shows how beautiful reality can be when presented completely without affectation and without recourse to retouching.

Amongst the older generation today, some work displays a stark realism; at the other extreme we find a whole school of surrealists.

There is also a school of journalistic photography, many of whose members produce work tending more to the illustrative than the documentary. Some aim to produce work that alternates between the poetic and the ironical.

A number of photographers of foreign origin have settled in France, and their influence has often been considerable.

Societies. Paris houses the oldest photographic society in the world, the Société Française de Photographie (French Photographic Society), founded in 1851 under the name of Société Héliographique and renamed in 1854. The Society brings together the most eminent personalities in French photography in the scientific, technical, industrial and artistic fields. It has a fine collection of apparatus and prints going back to the earliest times.

The French photographic industry is organized in an association, the Syndicat Général des Industries Photographiques (General Syndicate of Photographic Industries). The users of photography, professionals and dealers, belong to the Confédération Française de la Photographie (French Confederation of Photography). There is also the Syndicat National du Cinéma Sub-standard (National Substandard Cine Association), while some professional photographers belong to the Fédération Française de la Photographie (French Federation of Photography).

Amateur societies and clubs are organized in the Fédération Nationale des Sociétés Photographiques de France (National Federation of French Photographic Societies), which is a member of the Fédération Internationale d'Art Photographique (International Federation of Photographic Art). Several of these societies and clubs hold important international exhibitions.

Exhibitions. Every second year an exhibition of photographic equipment and products is organized in Paris, the principal French manufacturers and the French representatives of foreign manufacturers taking part. Since 1955 this exhibition, covering photography, cinematography, and the optical industry, has been held alternately in Paris and abroad. Its Paris home is the Grand Palais des Champs Elysées. Named the Biennale Photo Cinéma Optique, the exhibition has an average of about 300,000 visitors, and there are some 300 exhibitors from all over the world. The 1957 Biennale was held in Washington, U.S.A. A number of important meetings of an artistic and cultural nature are held during the exhibition.

A Salon National is held annually in the Mansard gallery at the Bibliothéque Nationale (National Library). It is confined to photographers of French nationality or resident in France and gives the opportunity of appraising the standard of French photography. After being shown in Paris, the prints from the Salon National are displayed in most of the larger provincial towns. The Coupe de France is an annual inter-club competition, the best photographs being exhibited in Paris and the provinces. The Centre International de la Photographie organizes international shows roughly once every three years and these shows also

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

tour the provinces. The Cabinet des Estampes of the Bibliotheque Nationale arranges exhibitions on specific subjects.

A number of scientific associations exist, corresponding to the numerous applications of photography. The majority of these associations concern themselves with both still photography and cinematography.

Study Centres. Two organizations take the lead in photographic research and teaching: the Institut d'Optique (Optical Institute) and the Ecole Nationale Technique de Photographie et de Cinéma (National Technical College of Photography and Cinematography).

The Conservatoire National des Arts et Métiers (Museum and School of Arts and Crafts) has a very fine collection of cameras and numerous daguerreotypes, and prints dating from the early period of photography. The Museum at Chalon-sur-Saône has some interesting items relating to Nièpce, and a fine collection of old cameras.

The Cabinet des Estampes (print-room) at the Bibliothèque Nationale contains the world's largest library of photographic prints, including numerous early works—amongst them the Nadar collection. As a copy of all photographs published must legally be deposited at the Bibliothèque, and many exhibition prints are likewise deposited, in particular those from the Salon National and the Coupe de France, this collection is constantly being added to. It provides the world's largest pictorial review of the whole history of photography, comprising more than 2 million prints with 500,000 now being catalogued. Prints are available for inspection by interested persons and copies may be taken from them. They are often loaned for display in exhibitions illustrating particular subjects.

The Société Française de Photographie also has a collection of historic photographs which may be viewed on request. It holds regular exhibitions in its gallery. There are a number of photographic print libraries open to the public (sometimes on application) in Government offices and other institutions, e.g., the Archives de France (Record Office), the Présidence du Conseil (Cabinet), the Documentation Française and the Centre National de la Recherche Scientifique.

Numerous French organizations and bodies make considerable use of photography thus contributing towards its progress, among them the Centre National de la Recherche Scientifique (National Centre of Scientific Research) the Institut Pasteur (Pasteur Institute), the Museum d' Histoire Naturelle, the Commissariat Général à l'Energie Atomique, the École Polytechnique, the various astronomical observatories and the Sorbonne University.

The Ministry of Education has set up a department of audio-visual studies as part of the Institut Pedagogique National. The department has its own laboratories and studios, and provides photographs and undertakes all kinds of research for educational purposes, besides giving instruction in photography for teachers of all grades.

During the Biennale exhibition of May 1955 it was resolved to set up an International Centre of Photography and Cinematography, with headquarters in Paris. Forty-three countries are represented in this organization, together with large international associations concerned with photography. It takes advantage of the presence in Paris of UNESCO and works in close collaboration with the United Nations.

The Centre organizes international exhibitions on general or specific subjects. It calls international conferences every two years, and these are held alternately in France and abroad. It also brings together international experts according to their work, especially in the following fields; studies in applied techniques, documentation studies, studies in picture psychology and sociology.

Publications. The following are the principal photographic publications in France: *Le Photographe* (official organ of professional photographers); *Sciences et Industries Photographiques* (technical journal); *L'Officiel de la Photographie* (organ of the Fédération Nationale des Sociétés); and the amateur magazines *Photo Cinéma*, *Photo Ciné Revue* and *Photo Monde*.

P.S.

Industry. The French photographic industry has shown considerable expansion during the past five years in the value of production. There are at present nearly a hundred producers established mainly in the Paris and Lyons areas. These together provide employment for an estimated 12,000 persons, the majority of whom are concerned with the manufacture of sensitized materials.

Among the equipment sector, which consists of about ninety producers with some 2,000 employees, the manufacture of still cameras is the most important single activity, whilst the production of cine apparatus and lenses has been undertaken for many years. Leading companies in this sphere are Ercsam, Heurtier and Pathe, whilst the firms of Angenieux and Berthiot are well known for their high quality lenses. Foca, Sem, Malik, Indo-Fex, and S.F.O.M. are the chief manufacturers of still cameras and projectors.

There are currently about seven producers of sensitized materials and chemicals, employing approximately 10,000 workpeople, the principal item of production being photographic paper. The leading company in the field is Kodak-Pathe, with 5,750 employees in 1963, whilst the other major producer is Lumiere, employing some 1,000 workpeople in 1963, both of these manufacturing sensitized paper, cine and roll film on a large scale. Other major producers are Gevaert (Pont-a-Marcq), Bauchet and Guilleminot which manufacture sensitized paper and film.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The industry is served by a trade association, the Syndicat General des Industries Photographiques et Cinematographiques Substandard (General Syndicate of the Photographic and Narrow Gauge Cinematographic Industries), which performs the function of representing manufacturers' interests in all commercial and Governmental matters.

The output of still cameras reached 628,000 units with a value of NF 40·4 million in 1963, the majority of which were accounted for by box-type models, whilst still projector production totalled 80,000 units worth NF 13·2 million. Within the total of other equipment and parts both cine cameras and projectors have increased in output since 1959, a large proportion of these being exported in contrast to still equipment, the bulk of which is taken up by the domestic market.

Sensitized material production has risen overall by more than 50 per cent in both volume and value during the last five years to reach 48·0 million square metres with a value of NF 422·8 million in 1963.

Approximately three-quarters of the total quantity in this year was accounted for by sensitized paper, with 35·7 million square metres, the output of which has shown substantial growth in the period, whilst still film has also been increasing in quantity, due mainly to graphic arts material, to a total of 4·0 million square metres in 1963. The output of X-ray film has remained fairly steady in the region of 3 million square metres each year since 1959, and cine film production has fluctuated about the 5 million square metres mark each year during the period.

Imports. The value of imported photographic goods has risen by over five times between 1959 and 1963 to a total of NF 226·4 million in the latter year.

Two-thirds of this figure is composed of apparatus, among which still cameras, particularly the miniature type, have gained an important place.

In 1963, imports of all types of still cameras reached a total of 467,100 units with a value of NF 41·0 million, the majority of which were supplied by West Germany with 206,100 cameras worth NF 27·6 million.

Imports of cine cameras have also shown a sharp increase in both quantity and value during recent years.

The bulk of these are currently amateur 8 mm. models, totalling 55,700 units valued at NF 14·3 million in 1963, of which the United States supplied 19,700 cameras worth NF 4·0 million and Switzerland 9,500 cameras with a value of NF 2·9 million. Cine projector imports have also expanded considerably, the 8 mm. models reaching 43,400 units worth NF 10·6 million during 1963, the chief suppliers being Austria (15,000 projectors worth NF 3·2 million) and Switzerland (7,900 projectors valued at NF 1·8 million).

Among other apparatus, photocopy equipment has become a major item, the chief sources in 1963 being (in NF million), the United Kingdom (20·3), West Germany (5·2) and the Netherlands (3·8).

Sensitized material and chemical imports have shown considerable growth over the last five years, although not holding such an important place as those of apparatus.

The principal item imported is photographic paper, totalling 9·3 million square metres with a value of NF 22·8 million in 1963, the main sources of supply being West Germany with 3·4 million square metres worth NF 7·7 million, and the Netherlands with 2·4 million square metres valued at NF 5·6 million. The Dutch paper is primarily photo-copying material for

Among other important products is roll film, office-copying machines and systems, the larger part of which is composed of black-and-white stock (totalling 0·6 million square metres worth NF 10·2 million in 1963), of which Belgium supplied 0·5 million square metres valued at NF 5·0 million.

Exports. Exports of equipment and materials have expanded by almost a half in value since 1959, reaching NF 158·2 million in 1963, the larger part of which is accounted for by sensitized products.

Among apparatus exported, the leading place is held by lenses destined for use with still and cine equipment. These amounted to NF 15·8 million in 1963, the largest purchaser being Switzerland, which took NF 9·4 million's worth during the year.

Cine cameras have gained an important position in recent years, reaching 5,400 units with a value of NF 6·1 million in 1963. Of this total, 8 and 9·5 mm. gauge models accounted for 4,300 units worth NF 2·2 million, the largest single market for which was the United States of America with 1,700 cameras valued at NF 1·7 million.

Exports of cine projectors have also recorded an increase since 1959 to 1,900 units worth NF 7·6 million, the larger part being accounted for by the 16 mm. type (1,100 projectors with a value of NF 6·8 million in 1963).

Still camera exports have fallen in value during the past five years to a 1963 total of 71,000 units worth NF 3·1 million. The majority of these are of the amateur type (70,000 cameras worth NF 2·0 million), and important purchasers are West Germany and Algeria.

The value of sensitized materials exported has recorded a considerable increase since 1959 to reach a total of NF 101·5 million in 1963. The leading product, cine film, totalled NF 44·2 million during the year, of which colour stock accounted for NF 27·5 million. The major purchasers of the colour reversal type are West Germany and Italy.

Another important item is sensitized paper, exports of which have more than doubled in both quantity and value over the period to reach

20·2 million square metres with a value of NF 24·4 million in 1963.

Leading markets for sensitized paper are Belgium, taking 8·7 million square metres worth NF 5·0 million, and West Germany, which received 2·5 millions square metres valued at NF 1·4 million during the year.

Among exports of the remaining products, roll film totalled 619,000 square metres with a value of NF 9·4 million in 1963, the bulk of this being composed of black-and-white stock (601,000 square metres worth NF 8·9 million), with Italy and the United States as chief markets.

G.R.H. & A.G.B.

FRAUNHOFER, JOSEPH VON, 1787–1826. German optician. After an early struggle became assistant and later partner in an important optical works. In 1814 he discovered a method of calculating a spherically and chromatically corrected objective. He also invented a machine for polishing large and mathematically accurate spherical surfaces. Between 1814 and 1817 he determined accurately the dark lines in the solar spectrum, since known by his name. He was the first to study diffraction with a grating and was responsible for producing high quality optical glass. Biography by M. von Rohr (1929).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

FREELANCE PHOTOGRAPHY

Practically every publication that prints photographs accepts a certain proportion of them from freelance workers. This means in theory that the scope of the freelance photographer is unlimited. In practice this is not altogether true, because the freelance photographer who tries to compete with the full-time agency and press photographers is unlikely to get very far. The regular photographers employed by the agencies and newspaper offices have facilities for transport, communication and publication that no freelance could afford. Furthermore they have a regular salary to tide them over their occasional failures whereas every time the freelance draws a blank, his expenses are a dead loss.

Scope for the Freelance. So in actual fact the freelance must narrow down his field of activities to the subjects which for one reason or another do not attract the agencies and the press. Very broadly this means avoiding anything of a topical or live news character and going after subjects of general and lasting interest. It means relying on inspiration and imagination more than the sporting calendar, the passenger lists of luxury liners and airlines and the police news.

This, at any rate, is where he makes a start; later on, if his work becomes known, he may be commissioned by editors who want his particular style of work on a topical or feature story. When that happens he may find himself working alongside the staff photographers but not in competition with them.

Even when he takes his camera along to photograph events of topical interest, the freelance approaches them from a different angle. While the regular cameramen are getting their pictures of the show itself, making sure of at least one good shot of every important person, and one of the principal event of the occasion, the freelance is looking around for the incidental stories—the faces of the onlookers, the lost child, or the puppy that slips through the police cordon at the crucial instant.

This does not mean that the freelance should ignore the regular subjects, only that he should keep his eyes open for everything else, too.

But most of the time the freelance concentrates on feature material where he has a chance of selling a number of pictures rather than one lucky shot. He keeps his ears and his eyes open for the ideas that it would not be worth the while of the pressmen to follow up, and when he travels he does so with the object of making a series of salable pictures. These he may send to appropriate weekly or monthly magazines, to travel agencies, or transport companies—e.g., airline, shipping, road, and railway.

Many freelance workers specialize in one particular kind of picture—e.g., animals, high speed flash, or landscapes—but the narrower their field of specialization, the less chance there is of their being able to make a living at it. By specializing and becoming known, there are many opportunities for the spare time freelance to make a profitable sideline of his hobby. But this is a different matter from turning it into a career.

Other Freelance Outlets. The scope of the freelance photographer is not limited to working for publication. There are other directions in which he can make money with his camera. He may make a profitable sideline of at-home portraiture, particularly of young children, a branch which few professionals trouble about. The professional naturally prefers people to come to his studio where he has everything standardized and under control. He is also spared the waste of time in packing and transporting his equipment. The freelance, on the other hand, has no studio anyway and does not have to add the extra time and trouble of working away from home to his costs. Some freelance workers with a flair for this type of photography have eventually opened up their own businesses.

There is also an outlet for technically sound freelance photographers in the commercial field. Small businesses and manufacturers of all kinds need photographs of their products for advertising, publicity, and sales literature. Very often the number of pictures they use in a year is too small to be worth the attention of a regular commercial photographer. By getting in touch with such small factories, shop-keepers and the like, the freelance can build up a useful connexion, but his main occupation must allow him to visit his various clients during their working hours.

There are also seasonal openings for freelances with their own cameras to work as beach and street photographers. But such jobs are strictly part-time work and not genuine freelancing. The photographer in such cases has to rely on the organization of the company that employs him; he could not afford to run the whole business himself.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

Freelancing as a Career. Freelance photography is not a difficult field to break into and anyone with a camera, a few rolls of film and a good story idea, may succeed at the first attempt. But to sell enough pictures month after month to earn a living, is a much more difficult matter.

The competition in the freelance field is keen because photography nowadays is a mass art. In the old days, people used to buy box cameras and content themselves with taking family snaps. Now they buy expensive cameras—often later models than most professionals possess—and start trying to earn spare-time money by submitting pictures to magazines and newspapers. When they get a few pictures published they often throw over their regular business to become full-time freelances. Most of them drop by the wayside because they mistake the ability to take a picture with the imagination to create or recognize one. They seldom develop a "picture sense", without which no freelance can go very far.

Some people are born with a picture sense, but most beginners have to acquire a picture sense the hard way—by working at it.

Anyone who wishes to become a successful freelance must study thousands of pictures other people have taken and analyse their weak and strong points. They have to take thousands of pictures themselves and learn to adopt the same critical, objective attitude to their own efforts. Most of all, they have to take their own cherished pictures around to editors and listen to their unflattering comments. Then finally they have to go back and try again until they begin to master the formula for turning out shots with above-average human interest.

Few people have the necessary tenacity. Most photographers who attempt freelance work discover that it gives them at best an erratic and unpredictable income and a lot of frustration. Economic pressure forces most of them to find a niche in a steadier, if less romantic branch of the profession. They open portrait studios, take baby pictures, go in for advertising or commercial work, or join the staff of some magazine or newspaper. A few strong individualists who prefer working on their own stick at it long enough to make a success of it.

For the average photographer freelancing is not a practical way of making a living. Even so, some of the best known and most successful photographers in the world do all their work on a strictly freelance basis and have done so from the beginning.

Submitting Prints. The prints should be dry mounted on card if possible so that they do not become dog-eared by being handled. Presentation is very important in any graphic art field and if a photographer does not respect his own work other people are not likely to take care of it either.

No freelance should ever show contact prints. Contacts should never leave the darkroom.

Every picture benefits from enlarging and trimming, while good retouching and finishing can improve the appearance of specimens enormously. Anyone who finds difficulty with this end of the job would be wise to get a specialist to finish his prints properly.

Every freelance should make up a rubber stamp with his name, address and phone number, and use it on the back of each print. It establishes identity, ensures the return of work and tells the editor whom to contact in the event of an assignment.

The freelance who wants to find his way into the high fee paying field must first carefully study the markets. Far too many send unsuitable material to an editor who then feels that his time is being wasted. A paper's or magazine's editorial policy should be examined until the freelance is thoroughly conversant with that journal's style. Photographs submitted should be sufficiently varied in format to allow the make-up department of the journal to arrange an interesting lay-out.

It is most important to send in prints at the time when the editor is looking for that particular subject. If the photographer is simply working through his print library and submitting likely specimens to suitable publications, the subjects must be appropriate to the issues then in preparation. With monthly magazines in particular, it should be remembered that the copy is made up several months in advance of publication. So there is no point in trying to sell Christmas pictures in December.

It must be made clear, when selling a picture, what rights are being offered—e.g., "First exclusive world rights", "First exclusive British rights", or "First Australian rights" or just "Publication rights". In the majority of cases the editor is only interested in normal publication rights. However, when exclusive rights are offered, the fee should be high enough to compensate for the sales that are being missed by ruling out other markets Editors seldom insist on buying world rights or transfer of copyright, but when they do they must be prepared to pay for it. Anyone unfamiliar with the marketing procedure should get in touch with a reputable photo agency who will handle the work on a commission basis if it has merit.

Basic Rules. Many budding freelances are discouraged because of their ignorance of the elementary requirements of the work. They may be able to take pictures, but that is all. Unfortunately there are other conditions to be complied with before the pictures can come to the notice of the right editor, be accepted, published and paid for.

It always pays to see editors in person whenever possible, rather than to submi work through the post or through an agent.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

There is nothing to be learned from a rejection slip but an editor's personal comments can be very illuminating—and helpful.

No one should pester editors for assignments at the outset. The way to attract their attention is to show them some good original picture stories; once their confidence is established, assignments will come automatically. But no editor wants to entrust an important job to an unknown, unproved cameraman. This explains why specimens are so important.

When a photographer has a good story idea, but cannot see the editor to discuss it personally, his best course is to put it down on paper and submit it in writing, rather than take it up with subordinates. A good editor can recognize a story at once and he may offer an assignment. If the idea is worth using the editor will be glad to pay for it and, even if the author's picture-taking ability is not up to standard, the editor may buy the idea and have one of his staff carry it out. The fact that the idea has been submitted in writing is protection against anyone using it.

It is a waste of time for a beginner to try to break into the top markets first unless he has some really outstanding pictures. He will be much more likely to get encouragement from editors of smaller publications which cannot afford to employ their own staff of photographers. Such editors are always looking for new talent. And the big markets will still be there when he is ready for them.

The freelance should never be shy about asking for credit-lines. A photographer has the same reason for wanting to be identified with his work as a writer. But unless the editor is asked at the time he may forget it and apologize later. The time to raise the question (and that of fees!) is before publication. H.B.

FREQUENCY. Number of complete events of a regular cyclic sequence, usually counted over one second. The term is especially applied to the wave propagation of the various forms of energy—e.g., electromagnetic and acoustic radiations, as well as regular mechanical movement.

The frequency is inversely proportional to the wavelength and proportional to the velocity of the radiation, e.g., if the velocity of a wave is 1,000 feet per second and its wavelength (measured from the crest of one wave to the corresponding point on the next) is 10 feet, then in every 1,000 feet there will be 1,000/10 = 100 complete waves. This number of waves is radiated every second, so the frequency is 100 cycles per second.

In the general case, the frequency n of a radiation travelling with a velocity of V and a wavelength λ is given by the equation

$$n = \frac{V}{\lambda}$$

V and λ must both be measured in the same units, i.e., metres per second and metres, or feet per second and feet.

It is more convenient to describe very short waves—e.g., of light and X-radiations—in terms of their wavelength in Angstrom Units. Radiations of longer wavelength—e.g., in the radio band—may be expressed in either wavelength or frequency. Much slower cyclic events are more conveniently expressed in terms of frequency.

Electrical energy is generally distributed as an alternating current—i.e., a current which alternates in a regular sequence between a maximum positive and a maximum negative value. The frequency of the alternations in Great Britain is almost always 50 cycles per second, but there are a few local exceptions. Elsewhere in the world the frequency of alternating current supplies varies but is mostly between 40 and 60 cycles.

There is no risk of damage involved in connecting heating equipment designed for one frequency to a supply of a different frequency, but the performance of motors and electronic equipment will be affected and in some cases the equipment may suffer.

Sound Frequency. The pitch of a tone depends on the frequency of the vibrations of the sound wave carrying it. In sound recording and reproducing equipment (e.g., tape recorders, amplifiers for sound cine projectors) the frequency range gives an idea of the performance—with certain qualifications. An average 8 mm. sound projector can reproduce a frequency range of about 80 to 6,000 cycles per second, a high quality tape recorder might cover 40 to 20,000 cycles, assuming loud speaker equipment, etc., that can handle such a range.

Spatial Frequency. In measurements of lens performance and resolution the line spacing of a test target (i.e., line pattern) is often expressed as a spatial frequency. Thus a target of 50 lines per mm. has a spatial frequency of 50. L.A.M.

See also: *Cycle; Wavelength.*

FREQUENCY RESPONSE. Term derived from audio engineering, indicating how an optical system or a sensitive emulsion (or a combination of both) reproduces detail of various fineness. The latter is specified in terms of spacial frequency, referring to the number of lines per mm. of a resolution test target. The number of lines resolved is plotted against the contrast of the image; the complete graph is

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FREQUENCY RESPONSE CURVE. This plots the contrast of an image obtained by a lens or lens and film system against the lines per millimetre resolved. Curve A indicates a high contrast at low spacial frequencies but a limited ultimate resolution. This corresponds to an image which looks brilliant and apparently sharp, but cannot resolve fine detail. Curve B represents lower contrast but higher limiting resolution. The image may look fuzzier but in fact shows more detail. For detail corresponding to a lower spacial frequency than the point X curve A represents better image quality despite its limiting resolution at Y.

known as the transfer function or contrast transfer function, and provides a fairly good indication of the performance of the system.

See also: *Information in the image; Lens performance.*

FRESNEL LENS. Short focus condenser lens of a special design used principally in spotlights. While a normal short focus condenser lens is thick and heavy, the Fresnel lens is relatively thin and light so it is less apt to crack from the heat of the lamp, which can be quite considerable.

The lens consists of a series of concentric stepped rings, each one being a section of a convex surface. The combined effect of all the rings is the same as that of a single lens of normal shape with the same diameter and curvature. Sometimes the lens is moulded in one piece, but for more accurate optical equipment it may be assembled from a number of optically ground curved prisms.

Fresnel lens patterns, embossed in plastic, are also used to distribute the image brightness over the area of a focusing screen. The screen may itself be the plane surface of the lens.

FRESNEL LENS. Used as a condenser lens in spotlights, it consists of a thin stepped disc with each step having the curvature of a much thicker lens.

FRESSON PROCESS. Early carbon printing process in which no transfer to a final support was necessary. It was similar to the Artigue process, but used a different type of paper.

See also: *Printing processes (Obsolete).*

FRIEDMAN, JOSEPH F., 1899–1956. American research chemist born in Russia. Emigrated to the United States in 1904, took Ph.D. in chemistry at Chicago University and joined the Ansco Corporation in 1943. Co-inventor with Edwin Land of the polaroid process. Dr. Friedman also played a leading part in the development of Technicolor. His *History of Colour Photography* (1944) is a standard work.

FRIESE-GREENE, WILLIAM, 1855–1921. English professional photographer, and one of the pioneers in motion picture photography. Patented (with Evans) a "machine camera" in 1889 which took instantaneous photographs in rapid succession. He was a prolific inventor; his patents include a two-colour additive method of colour cinematography. Biography by Ray Allister (London 1948).

FRILLING. Fault caused when an emulsion separates from the edges of the support, generally because of some abnormality in the temperature or chemical composition of the processing solution. The loose gelatin swells and expands, causing it to crinkle and form a characteristic frill.

Frilling seldom occurs with modern sensitized materials. It is usually the result of very high temperatures in processing—and violent changes in solution temperature. Another possible cause of frilling is the use of strong acid rinses or stop-baths immediately after the film has been in a strongly alkaline developer. Excessively long immersion times in solutions can be another cause.

Frilling is also troublesome in carbro printing during the development or transfer of the gelatin relief image. The cause in this case may be high temperatures, excessive immersion times, or an insufficiently wide border on the original bromide print.

See also: *Blisters; Faults; Hot weather processing; Tropical photography.*

FRITH, FRANCIS, 1822–98. English landscape photographer from 1853 onward; partner in a Liverpool printing firm which moved to Reigate in 1859, when a photographic printing department was added. Frith produced a large number of photographically-illustrated books with views taken on three extensive tours of Egypt and the Near East 1856–60. Also issued portfolios of photographs of many West European countries. Frith & Co. became the largest photographic publishers of English and foreign views in the world, their catalogues listing several hundred thousand pictures.

CC-0. Ancestry.com Digital Preservation Foundation, Unknown

FRONT ELEMENT FOCUSING. Method of focusing in which the front component of the lens is moved in or out to focus the image.

FROST. The photographic possibilities of frost are mostly confined to pictures of trees and bushes white with rime and to records of the frost patterns on window-panes. With the first type of subject a filter must be used when blue sky is included in the picture or the frost-whitened branches and twigs will tend to merge with the sky above the line of the horizon. As frosty subjects of this sort are generally photographed in dull, overcast weather (the rime quickly disappears in sunshine), the contrast of the negative may have to be exaggerated by prolonging development.

Frost patterns on window-panes are best photographed from the inside against a background formed by supporting a sheet of black cloth or dull black paper at 45° outside the window. The room should, at the same time, be darkened except for the one window to guard against unwanted reflections.

The most beautiful effects with frost patterns are obtained by photographing them as large as possible. This can be done by normal close-up or macrophotography techniques.

For photography in frosty weather the lens of the camera should be at the same temperature as the air, or it will mist over and give a blurred image. For this reason the camera should not be carried in an inside pocket if it is to be used for taking photographs in the open air. A warm camera taken out in cold air tends to form mist on the inside of the lens. The lens of a cold camera, brought into a warm room, tends to mist on the outside. P.J.

See also: *Cold weather; Snow.*

FROST DEFORMATION PROCESS. Process employing a photoconducting thermoplastic film on which an electrostatic image is produced and which upon heating is deformed by the electrostatic change in the corresponding image areas to form a light-scattering image.

See also: *Thermoplastic recording.*

FUNNEL. Aid to pouring liquids into narrow-necked bottles. It consists of a hollow stem, widening out into a flared conical shape.

Funnels may be made of glass or plastic; the latter less breakable. Pliable plastic funnels (polythene) are particularly useful.

The neck of the funnel should be ribbed, so as to leave an air space when it is inserted into the neck of a bottle.

Funnels can also be used for filtering; in that case a filter paper or a plug of cotton wool is inserted in the top.

Most conical funnels flare out at an angle of 60°. The size is specified by the diameter at the top. For most photographic purposes a 4 ins. (10 cm.) funnel is a suitable size.

FUSE. Safety device consisting of a deliberate weak link in an electric circuit designed to break the circuit when the current exceeds the safe working level. Usually the fuse is a short length of easily fusible wire (hence its name) inserted in the circuit in the form of a cartridge, or wired across a pair of contacts fitted to a porcelain holder.

If the circuit becomes overloaded (either through a short-circuit of bare wires touching, or through connecting across it more lamps or other gear than it can carry) the wiring heats up. The fuse then melts and breaks the circuit before any other parts of the wiring can heat up sufficiently to do any damage.

Open wire fuses can be repaired easily by just replacing the molten piece of wire. The correct gauge of fuse wire should always be used. With cartridge fuses the whole cartridge must be replaced. If the fuse blows again immediately, the wiring of the circuit or the appliances in it must be checked for faults.

FUSE RATINGS

Type of Circuit or Appliance	*Type of Fuse*	*Rating (Amps.)*	*Location of Fuse*
Amplifiers, and other individual low power appliances	Cartridge	2–3	In appliance
Projectors and other more powerful units	Cartridge	5	In projector
House lighting circuits	Porcelain	5	In fuse box
Power circuits	Porcelain	10–15	In fuse box, sometimes in power socket
Main collective house circuits	Porcelain	20–60	In special fuse box; sometimes these are service fuses and must be repaired only by service staff of electricity suppliers
Individual power units (heaters, etc.) with fused plugs	Cartridge	3–13 (according to appliance)	In plug

When replacing or repairing fuses, the rating must never exceed that of the blown fuse. If a heavier fuse is inserted in the circuit, it may be able to carry a greater load than the rest of the wiring and is then no longer a weak link; i.e., it is useless as a safety device.

Common fuse ratings are shown in the table above. The heavier fuses and those covering the lighting and power circuits of a flat or house are generally installed in fuse boxes with a main switch. The box can only be opened when the circuit is switched off. In the case of cartridge fuses or fuses in individual appliances the equipment must be disconnected from the electricity supply (not just switched off) before attempting to replace or repair the fuse. L.A.M.

G

GAIN (PROJECTION). Measure of the useful brilliance emitted by a projection screen in relation to the intensity of the illumination falling on it. When a perfect diffuse reflector or (back projection) transmitter, illuminated by a light intensity of one foot candle, has an apparent brightness of one foot lambert, its gain is unity in all directions.

As no screen will diffuse or reflect all the light falling on it, the gain of a screen is always less than unity, although directional screens may have a gain of more than unity over a narrow zone immediately in front.

See also: *Projection principles; Screens for projection.*

GALVANOGRAPHY. Term applied to photographic processes in which a photographically-produced relief image is given a conducting coating of black lead and then heavily electroplated to form a shell. This then can be backed up with type metal to form a printing plate for photomechanical reproduction.

GAMMA

Gamma is a sensitometric quantity derived from the characteristic curve of photographic emulsions. It is loosely interpreted as a measure of the contrast reproduced in a negative image, i.e., the ratio of negative contrast to original subject contrast for a given range of tone values. Such a comparison is based on the assumption that the brightness values of the subject tones can be accurately measured, and that the corresponding negative densities fall within the straight-line portion of the characteristic curve—a condition rarely fully satisfied in practice. Gamma is often also quoted as a yardstick for the degree of development, especially when film manufacturers recommend development times for their materials. In that sense it can be said that negatives developed to the same gamma show comparable tone reproduction.

In technical terms, gamma (written γ) stands for the slope or inclination of the straight line part of the characteristic curve. Mathematically it is defined exactly like the slope of a railway line—i.e., as the ratio of the height gained to the distance travelled in a horizontal direction. In our case the height is density (D) and the base is the log of the exposure (E). So $\gamma = D/\log E$.

Gamma is important to the photographer because it tells him how his photographic material will respond to a change in exposure. In a material with a low gamma, a small change of exposure will produce a small change in density; but the same small change of exposure with a high-gamma material will produce a much larger change in density.

Materials capable of widely different gamma values are available. The particular type of material that the photographer chooses depends on how he intends to translate differences in brightness of the object—and hence differences in exposure—into differences in density on the film, plate, or paper. If the brightness differences—i.e., the tone range of the subject—are small, he chooses a material of inherently high gamma. If they are large and he wishes to record the total range of exposures, he chooses a low gamma material.

Negative Materials. In practice each of the main groups of negative materials has its own very definite gamma characteristics.

Normal photographic subjects call for films and plates with a gamma value of around 1·0, varying from 0·6 to 1·5. This enables the emulsion to record the wide range of tones which occurs in an outdoor scene. When printed on a material of similar gamma value, the print will be as true a reproduction of the original as is possible. The exact condition for this occurs when gamma (negative) × gamma (positive) = 1. This is known as the Goldberg condition.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

GAMMA AND CONTRAST. Top: *A negative of gamma unity reproduces the subject tones as corresponding image opacities, with the image being of the same contrast as the subject.* Bottom: *A negative of high gamma reproduces only a limited range of subject tones, and exaggerates the contrast.*

X-ray records have to be made on very sensitive films of high gamma. Here the image has inherently very low contrast, and a high gamma material enables the radiographer to reproduce the small differences in log brightness as much larger changes in density, thus increasing the sensitivity of the method. X-ray films may reach gamma values of well above 3.

Document copying and process work require materials of even higher gamma values. Here it is only necessary for the photographic material to record two tones: black and white. Often a typed letter represents quite small differences in log exposure which are turned into large differences in density in the copy.

For process work, the differentiation between black and white must be as great as possible. Materials with gamma values between 5 and 10 are available for this purpose.

Printing Papers. To match the films and plates mentioned, there are photographic papers with a correspondingly wide range of gamma values. Gamma values are not, however, commonly quoted for papers, since it is not usual to confine the image to the straight-line portion of the characteristic curve. Average slope figures are used instead. These may be taken, for example, between two points on the curve where the slope is one-tenth of the average slope.

Most papers for the printing of snapshots, etc., are divided into 4 to 6 grades, the slopes of which match the range of the negative materials used for this purpose. Papers described as soft or normal will make a good print from a negative developed to a gamma of around 1 and their slope figure is of the order of 2. Very soft papers have slope figures of half that value, and very hard papers may have slopes half again as great. Papers for document and process work are harder still and slope figures are not as a rule quoted.

These references to the slope values of papers must not be misunderstood. As a rule a paper is not chosen because it will give satisfactory tone reproduction from a given negative, but simply because its useful exposure scale is identical with the density range of the negative. More exactly, the paper is chosen because its useful exposure scale covers that part of the density range which the photographer wishes to reproduce in his print. This choice ensures that he will make use of the full range of tones from black to white that the paper is capable of reproducing. It means also that the relative tone values, far from being faithfully reproduced, are in most instances falsified.

Gamma Control by Processing. The gamma value of a photographic material is not fixed and can often be varied within wide limits by the method of development and the choice of developer. In general, gamma is low for short times of development or if the temperature of the developer is low. As the time of development is increased, gamma values rise until they reach an optimum value which is known as γ_∞ (gamma infinity). The plot of gamma against time of development is known as a gamma-time curve; such curves are often plotted for a range of times of development.

The type of developer used also affects gamma. The highest gamma values are obtained with very alkaline developers containing hydroquinone and sometimes no other developing agent. Fine-grain developers, such as buffered borax metol-hydroquinone developers or developers based on p-phenylenediamine, will give low gamma figures. By a suitable choice of developers and developing conditions gamma values varying between 1·5 and 3 may be obtained, for example, on the film used for document micro-copying.

Information on the relationship between gamma and development is generally stated in the manufacturers' descriptive literature, but where high accuracy is required such information must not be taken too literally. There may be variations between batches of the material and the conditions of development, agitation, etc., may not be the same—e.g., in the development of separation negatives.

Separation negatives must be developed to the same gamma figure but gamma often changes with the colour of the exposing light. So any natural variation in gamma with the colour of the filter must be compensated for by changing the time of development. This means

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

GAMMA AND LIGHT COLOUR. The gamma obtained on a panchromatic material varies with the colour (wavelength) of light. This variation may be as much as 0·4 from blue to red.

that the photographer must determine gamma-time curves under his own conditions which he must keep rigidly constant throughout.

Gamma and Wavelength. With many materials gamma changes with the colour of the exposing light. Materials behave differently in this respect and no general rule can be given, but usually the gamma value for a material exposed through a blue filter is lower than those for green and red filters. For ultra-violet light, gamma figures drop even lower, a fact which causes considerable difficulties in spectrographic work. The change is caused by the difference in absorption of the light by the photographic emulsion. With ultra-violet the absorption is so strong that only the top layer of the emulsion receives any light at all.

The only way of preparing a sensitive material which has uniform gamma throughout the spectrum is to add to the emulsion a screening dye with an absorption spectrum complementary to that of the emulsion, so that the total absorption is constant at all wavelengths. This yields a constant-gamma material.

Variable-gamma Materials. Many workers like a printing paper with a gamma or slope which they can alter at will so that they can print negatives of widely different contrasts without having to use different grades of paper. Papers of this type are in fact marketed by several manufacturers. They are prepared from a mixture of two emulsions, one hard and the other soft. One is dye-sensitized—e.g., to blue and green light—whereas the other emulsion may be sensitive to blue light only. By changing the colour of the enlarging light with different colour filters the proportion of the total exposure given to each emulsion can be controlled at will. With some materials a range of specific filters is supplied, one for each contrast grade. Alternatively, a single filter may be used to give one extreme of contrast, and the material exposed partly with and partly without the filter for intermediate gradations. In this way a selection can be made from the two emulsions, giving a range of contrasts equal to that normally covered by four or five separate paper grades. W.F.B.

GAMMA RADIOGRAPHY. Radiography using gamma rays, instead of the normal X-rays. Gamma rays are emitted by radioactive bodies and have a shorter wavelength than X-rays—i.e., around 10^{-10} cm.—they are therefore more penetrating. This form of radiography is now extensively used in industrial non-destructive examination of castings, welds, and moulded parts.

The most widely employed sources of gamma radiation are radium and the gamma-active isotopes produced in atomic reactors. These are supplied in the form of cylinders of 1 to 6 mm. of isotopes of metals such as antimony, cobalt, iridium and tantalum. The gamma energy of the source and its other properties—e.g., half-life and activity per grain—are specified according to the type of specimen to be inspected.

One of the principal advantages of isotopes as a source is that they can be used in positions where it would be impossible to accommodate an X-ray tube—e.g., inside pipes and on welded girder-work.

The technique is simple: an X-ray type of film in a holder, usually sandwiched between lead foil intensifying screens, is placed against the subject, and the isotope is uncovered on the opposite side so that the radiations pass through the subject before falling on the film. By suitably choosing the characteristics of the source and the time of exposure, the resulting image reveals variations in the internal structure of the specimen—e.g., flaws, scale inclusions, and cavities in welds and castings.

Where a number of small items have to be examined in this way, the isotope is simply surrounded by any number of specimens, each one associated with its own film and screens. All are then exposed at the same time.

Isotopes for gamma radiography are dangerous to handle; they are normally supplied in lead bombs which are opened from a distance with tongs or other remote handling equipment only when everything has been placed in position and no one is left within range. The exposure is made by uncovering the isotope and leaving it—often for a day or more—in a locked room surrounded by the specimens to be radiographed. At the end of the calculated exposure time the bomb is again closed up before anyone is allowed near the specimens.

Gamma radiations are used in the treatment of cancer but not normally for the radiographic examination of the body.

See also: *Industrial radiography.*

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

GAMMA RAYS. Radio-active radiations similar to X-rays but of a shorter wavelength and hence greater penetrating power. Gamma radiography with isotopes is now an important department of industrial radiography.

See also: *Spectrum.*

GARDENS. Any attempt at conveying the size of a large garden generally results in extensive areas of uninteresting foreground. The massed flowers and main features of the small garden—lily pond, pergola, rockery, etc.—are generally laid out on a more modest scale that is easier for the normal angle lens to handle.

Viewpoint. Generally it is better to choose characteristic portions of the garden rather than try to include the whole scene, and all stiff and formal effects should be avoided. Nothing is less attractive than a square-on photograph of a flower bed or border where a narrow uniform strip of flowers stretches from one side of the picture to the other. Straight-down-the-garden-path pictures are equally dead looking.

A viewpoint on a corner usually gives a picture in which the space is filled in a much more interesting fashion; paths then lead into the scene at an angle, and the varied masses of light and shade formed by groups of flowers can be balanced to make a pleasing and original composition.

A camera at eye-level will lessen the importance of the closest blooms, but indicate size of bed and general layout. For distances of 10–20 feet, waist-level viewpoints are often best; much depends upon the varying heights of the flowers themselves, whilst for small border clumps camera heights of 1 to 2 feet at distances of 4 to 8 feet are advised. Dead-overhead viewpoints of selected, even-growing masses, provide interesting "pattern" pictures.

It is often possible to find an effective viewpoint in which a view of the garden is seen from indoors through an open french window or door. And interesting photographs can often be taken from a first floor window—a viewpoint which, in many cases, has the advantage of excluding the sky.

Garden Plants, Trees, Shrubs. Rockeries and massed blooms are easier to arrange in the picture space than isolated clumps of assorted specimens.

In black-and-white pictures, the flowers of the lightest tones should be placed to provide the main point of interest, but in making colour photographs the place of interest should go to the most brilliant colour.

Plants that carry all their interest at the top—like standard roses—are not easy subjects unless they are photographed close up. Flowering shrubs and fruit trees are good space-fillers for upright or square picture shapes. Dark shrubs and laurels make poor subjects lacking interest but are excellent for backgrounds.

Garden Furniture. Garden features like archways, bird baths, sundials, steps and the like make excellent units for framing or furnishing the picture space, while ornamental loggias and lily ponds make good main features. Rustic furniture, especially when it is new and shiny, is risky picture material. Statues and animals are best kept out of the picture as they attract all the attention and the garden becomes a mere setting for them.

Backgrounds. The majority of garden photographs are spoiled by aggressive backgrounds—white painted trelliswork, wire-netting, railings and ugly fencing. It is usually difficult to avoid this type of background but it is possible to play it down—it can be blurred by selective focusing and the picture can be taken when the background is in shadow.

On the other hand, close-boarded fencing, wattle and old roughcast walls can actually add decorative interest to the picture if the lighting is oblique and shows up the texture.

The sky, usually the best of backgrounds, is rarely effective in a garden photograph and is generally better cut out altogether by a suitable choice of viewpoint.

Many garden pictures are marred by details that could easily have been avoided before the picture was taken—dead or withered blooms near the camera, stakes and canes, name-tags and odd tools. Daisies that pass unnoticed on the lawn come out as disagreeable white spots on the print.

Lighting. The best lighting is provided by slightly diffused sunshine with plenty of reflection from white clouds. This type of lighting gives modelling and relief without dense black shadows.

Flat, high angle or fully frontal lighting all tend to destroy modelling and depth, while back lighting is rarely effective, particularly when it shines through a network of small branches.

Filters are not required unless the flowers are tall, and are photographed against a blue sky background, when a 2 × or 3 × yellow, green, or yellow-green filter may be used with advantage. An orange filter gives greater tonal contrast, but at the expense of over-dark foliage. Broad lawns and open scenes which include the sky also need a filter.

Early morning and evening sunshine is useful for spotlighting individual features, but it should always be supplemented by a white reflector or the shadows will be solid black.

Camera. All the normal types of camera are suitable for garden photography. Even a fixed focus camera will turn out attractive garden pictures, but it calls for even more attention to the background than usual. A focusing camera has the advantage that it can be made to throw the background out of focus. P.J.

GARDNER, ALEXANDER, 1821–82. American photographer born in Scotland. Emigrated in 1856 and assisted Matthew Brady, first in his New York studio and from 1858 as manager of his new Washington studio. During American Civil War, worked first on Brady's staff of war photographers then in document and map copying department of the Federal Army of the Potomac. At the same time, Gardner and other former employees of Brady took some of the most famous Civil War photographs. One hundred of these were published in *Gardner's Photographic Sketch Book of the War*, (1865). In 1863 Gardner opened his own portrait studio in Washington. In 1868 he became official photographer to the Union Pacific Railroad Company. In 1873 he made a portrait collection of criminals for the Washington police.

GAS BURST AGITATION. System of stirring up processing solutions in tanks by means of nitrogen gas led into, and released near the bottom of, the tank in periodic bursts.

See also: *Agitation.*

GASLIGHT PAPER. Old name for contact paper, derived from the fact that it was designed for printing by artificial light, and introduced at a time when gas light was the normal artificial illumination.

See also: *Papers.*

GATE. Part of the cine camera and cine projector in which the film is held during the exposure or projection respectively of each frame. The term is derived from the construction of the gate in early and many current instruments, where a hinged plate or frame with an aperture swings into position over the film.

The gate incorporates guides to keep the film flat and in alignment, to avoid gate float or unsteadiness in the moving picture during projection. The guides hold the film by the edge only to prevent scratching. The gate is one of the most precisely machined parts of the camera or projector, and must be polished to a highly smooth finish. The aperture in the gate, the so-called gate mask, defines the area of the film projected on the screen. The dimensions of the gate mask are laid down by international standards.

By derivation, the picture stage in a slide projector is frequently also known as the gate, though its mechanical construction differs appreciably from that of a cine projector.

See also: *Cine camera; Projector (cine).*

GAUDIN, MARC ANTOINE AUGUSTINE, 1804–80. French photographer, optician, and scientist. Improved the daguerreotype process. Achieved the first instantaneous exposures in 1841. Investigated (1841) the Becquerel effect. Studied gun cotton (1847) and silver halide collodion emulsions (1853, 1861). Proposed (1853) potassium cyanide as fixing agent, gelatin and other substances as image carriers. Described (1861) an improved collodion emulsion for negatives.

GAUMONT, LÉON, 1863–1946. French pioneer of the cinema. In 1895 became director of the Comptoir Général de Photographie and marketed the Demeny-Decaux Chronophotographe. This was followed by other cine apparatus for professionals and amateurs and by still cameras, development machines, synchronized sound-and-film apparatus (Chronophone 1910), three-colour additive cine projection apparatus (Chronochrome 1912), and the Ideal Sonore sound film method (1929). Important film producer.

GAUSS POINT. Point on the optical axis of an objective situated at a distance from the focus equal to the focal length of the equivalent simple lens. There are two such points, one for the lens used normally, and one when it is reversed. Also commonly known as the nodal points.

See also: *Lens.*

GAY-LUSSAC, JOSEPH-LOUIS, 1778–1850. French chemist and physicist. Experimented on photochemical reactions, among them that between chlorine and hydrogen (1809). In 1839 he made the report on the discoveries of Daguerre for the Chamber of Peers at the same time as Arago reported for the Chamber of Deputies. Suggested, with Arago, the possibility of producing maps photographically.

GELATIN. A naturally occurring protein used as the binding medium for the silver halide crystals in the common type of photographic emulsion. It is isolated from animal skins and bones by various processes, which have considerable influence on the properties of the product.

It is insoluble in cold water but will absorb about 10 per cent of its weight of water, with consequent swelling. Hot solutions will set to a rigid jelly at certain temperatures, and this is one of the properties which is useful in the manufacture of photographic emulsions. It is not, however, a definite chemical compound, and a given sample of gelatin will contain molecules of various molecular weights, ranging from about 20,000 to over 100,000, and of various amino-acid compositions.

As a protein it has both acid and basic properties. It can also combine under certain conditions with some heavy metal ions to form insoluble products. Some photomechanical processes are based on the light-induced hardening of gelatin. For example, the action of light on a gel containing potassium dichromate leads to the formation of a compound which is insoluble in water. Washing with

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

warm water removes the unexposed areas, leaving a relief image. Gelatin is also hardened by other agents, including formaldehyde and the oxidation products of some developers.

An important photographic property of gelatin is its protective colloid action towards the silver halide crystals during the preparation of an emulsion. If aqueous solutions of silver nitrate and a potassium halide are mixed, the solution becomes opalescent, but the gelatin prevents the crystals from growing sufficiently to be precipitated. In the absence of gelatin the silver halide is precipitated as crystals which are too large for photographic purposes.

A property of gelatin directly connected with the actual photographic process is its role as a halogen acceptor. The action of light on a silver halide leads to the formation of atoms of silver and of the halogen, which can recombine to form the original silver halide and so nullify the effect of the light. This recombination can be prevented by the addition of compounds which combine with the halogen, and gelatin itself is such a compound.

One of the earliest materials used as a binder for silver halides was collodion, or cellulose nitrate, on which the "wet collodion process" was based. In 1871, however, gelatin was found to be a good binding medium, and had the advantage over collodion that emulsions made with gelatin were much more sensitive, and were also sensitive when dry. Not all gelatins however gave equally sensitive emulsions, and the "good" photographic gelatins were found to contain a few parts per million of certain sulphur compounds. The addition of such compounds, for example allyl thiourea, to "poor" photographic gelatins enabled sensitive emulsions to be obtained. Nowadays photographic gelatins are of high purity and the sensitizing compounds are added in controlled amounts.

Synthetic polymers, such as polyvinyl alcohol and polyamides have been proposed as substitutes for gelatin, but none has proved completely satisfactory as yet. Where wet processing is not required, as for some print out-recording papers, materials such as polystyrene have been used as the binding medium. E.M.

See also: *Emulsions; Sensitized materials manufacture.*
Book: *Photographic Gelatin*, by F. G. Clegg and R. J. Croome (London).

GELATINO-. Prefix once applied to certain photographic processes and materials—e.g., gelatino-bromide process, gelatino-chloride paper—indicating the employment of an emulsion of light-sensitive chemicals in gelatin. The use of the prefix was more general at the time when gelatin emulsions were replacing collodion for normal photography.

GELATIN-SUGAR PROCESS. Daylight printing process in which the action of light produces selective hardening of a sensitized layer of pigmented gelatin and sugar coated on a paper base. The image is developed by washing away the unaffected material with hot water. The process is almost identical with the gum bichromate process.

GENRE. Term for the type of photograph that depicts people in their normal environment of work or leisure.

The essence of genre is its unaffected portrayal of the everyday life of average men and women. Photography of this type is only successful when the whole feeling is natural and unforced.

GENTHE, ARNOLD, 1868–1942. American portrait photographer born in Germany. Settled in San Francisco 1895, took up photography as a hobby and in 1897 opened a professional portrait studio. Made excellent pictures of the Chinese quarter and of the earthquake and fire in 1906; also of his many travels in foreign countries. Moved in 1911 to New York where he was prominent as a photographer of stage and film actors and other celebrities. Autobiography: *As I Remember* (1937).

GEOLOGY. Geology is the study of the rocks which make up the earth's crust and includes as sub-divisions mineralogy, palaeontology, crystallography, and the specialized study of metal ores. Technically a rock is any substance forming part of the earth's crust; even such substances as coal and peat are rocks to the geologist.

Field Work. Any part of the globe where natural rock is exposed is a suitable site for a geological investigation. Nowadays a great deal of the geologist's work consists of laboratory examination of specimens collected in the field and his records, as a result, consist largely of photomicrographs and macrographs of material specially prepared.

These records are not complete, however, without a certain amount of descriptive illustration of the locality and site from which the material was obtained. To complete the record photographs are usually desirable to show the topography of the terrain, the general configuration, bedding, etc., and direction and angle of dip (if any) of the exposed rocks. Photographs of any usual or unusual features are taken which, used in conjunction with a map, give the reader a fair idea of what he would actually see on arrival at the site.

The photographic apparatus carried should be as small and light as possible in view of the other equipment the geologist must carry. Any good film camera is suitable. A reflex is useful, but a miniature or folding roll film camera is more convenient. It must be borne in mind that a certain amount of scrambling over rough ground may have to be done and a secure, well-fitting camera case is essential.

Preparation and Technique. When photo-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

graphing large expanses of exposed rock, it is obviously not practical to put in a great deal of preparatory work on the surface, but a fair amount of help can often be obtained from local conditions, if used to best advantage. On a weathered surface, for instance, the harder rocks or layers, being less worn, protrude beyond the surface of softer rocks. Cast shadows will show up such formations in strong relief at certain times of the day.

Some idea of the size of the rock exposure should be recorded by including in the photograph a familiar object of known size. The geologist's hammer will serve if it will be sufficiently visible in the photograph; for more extensive exposures, a walking stick painted alternately black and white in 6 ins. sections along its length is commonly used.

When a site has been selected—e.g., a cliff face showing structures such as bedding—it is not advisable to photograph it in direct frontal lighting, as a good deal of the bedding which is faint will not record well. When possible, the site should be photographed when the light is falling at an oblique angle, thus forming a certain amount of shadow and exaggerating the structure. From small structures which have been badly weathered, loose grains and vegetable matter should be brushed away to reduce confusion in the photograph.

Where colour variation is the main feature in a rock exposure, it is generally necessary to use a panchromatic emulsion with a suitable filter to record colour differences faithfully. 35 mm. colour film has also been employed successfully for this purpose. The primary object of photography in the geological field is the production of a true and accurate record; the claims of an aesthetically pleasing picture and observance of the laws of composition must always be of secondary importance.

It is advisable where possible to take several shots of a site from different angles. These give a far better idea of the general lay-out than one comprehensive view.

Panoramas. Reasonably pleasing panoramic views can be produced without the aid of a special camera if certain basic points are observed. These are:—

(1) The number of exposures must be adequate to cover the area being photographed and an overlap of at least 25 per cent is normally allowed from one exposure to the next.

(2) The camera should be rotated through the necessary arc on an imaginary axis passing through the lens assembly. Mounting on a tripod is usually accurate enough for most purposes.

(3) The base of the focal plane should be in the same horizontal plane throughout.

(4) Exposures should be made in rapid succession, care being taken that moving clouds or other factors do not cause a variation in lighting conditions.

(5) The prints should all be made at the same time, each print being carefully developed to the same density as its immediate neighbours. They are assembled into a panorama by mounting on cardboard and roughly tearing the overlapping print at the matching point so that a chamfered edge is obtained. The tear is so made that the chamfer occurs on the underside of the overlapping prints. By using this procedure the uneven edge of the tear will normally be almost invisible if the prints are well matched for density.

Hand Specimens. Where the macroscopic structure of the specimen is of interest, the face to be photographed should be as flat as possible and, if necessary, should be ground flat or polished. This is done by grinding with successively finer grades of abrasives, preferably in powder form moistened to a paste, on a flat surface until the required degree of detail in the surface of the specimen is visible. With a fossil, however, the shape and any signs of distortion are as important as the surface features and there should be no trimming or grinding of the surface. It should, however, be cleaned up to show the surface features to best advantage. Particles of the sedimentary rock surrounding the specimen should be picked out with a scriber or similar instrument, and the surface to be photographed brushed clean before photographing.

Sometimes only the one surface is exposed and the specimen is left attached to a portion of its groundmass; at other times the specimen is picked clean and photographed against a black or white background. The treatment is a matter of individual preference, but it also depends on the nature of the specimen—e.g., it may be necessary to keep the specimen on its groundmass in order to keep it whole, just sufficient of the surface being picked and scrubbed clean to show the detail.

Photomicrography. If the rock structure is too fine to record macroscopically, a thin section can be prepared and magnified by transmitted light through a microscope.

The preparation of the thin section requires considerable skill and patience. One side of a small piece of rock is ground with fine carborundum powder to give it a very smooth surface. It is then mounted on a glass slide with Canada Balsam. The other side of the specimen is then ground with successively finer abrasives until it reaches the required degree of thinness. By polarizing the light through the microscope the thickness of the section is indicated by the colour of the crystals. From this colour the thickness can easily be determined with the aid of the polarization colour scale.

Finally the thin section must be covered with Canada Balsam and then protected by a cover glass.

Photographing the Thin Section. A petrological microscope is necessary for photographing thin sections since a great deal more detail and

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

structure can sometimes be seen by using polarized light.

Photomicrography is a skilled art and it is normally desirable to use an instrument specially designed for this work. Some 35 mm. cameras can be used and the manufacturers supply a special adaptor for this purpose. Provided certain rules are observed, it is possible to arrange a suitable plate camera and a microscope for satisfactory results.

Normally petrological work does not call for a high degree of magnification, but the mining geologist frequently uses very powerful objectives when examining polished ore-minerals, and photographing these specimens with the aid of a vertical illuminator can be very difficult, even with a specially constructed instrument.

All types of emulsion are used in this work, ranging from process to panchromatic, depending on the degree of contrast required and the presence or absence of colour in the specimen.

M.C.K. & D.G.W.

GERMANY

An important part in the invention and progress of photography has been played by Germany, and today photography in the Deutsche Bundesrepublik (German Federal Republic, West Germany), as well as being a recreation for millions of amateurs and an indispensable aid to most branches of science, engineering, and commerce, provides the basis for a flourishing industry with a world-wide reputation.

Discoveries in Chemistry. 1193–1280: Albertus Magnus (Albert von Bollstädt, a Dominican monk), one of the most learned men of the middle ages, was the first to draw attention to the blackening of silver salts when in contact with organic substances. ("A silver nitrate solution dyes human skin black, and the dye is difficult to remove.")

1565: Georg Fabricius was the first to discover the existence of silver chloride as a natural mineral and to describe it.

1683–1737: Kaspar Neumann was the first to give details of the sensitivity of mercury salts to light.

1725: Johann Heinrich Schulze discovered that silver salts are sensitive to light. Published his discovery, 1727.

1782: A. Hagemann gave the first definite details of the sensitivity of gum to light.

1801: Johann Wilhelm Ritter discovered the ultra-violet rays of the spectrum and their darkening effect on silver chloride and was the first to observe the conflicting effects of red and violet rays.

1814: Nicolaus Wolfgang Fischer discovered that silver albuminate is sensitive to light and ascertained further facts about the light sensitivity of silver compounds.

1819: Theodor Freiherr von Grotthuss enunciated the law of photo-chemical absorption and elaborated the theory of chemical reactions to light.

1831: Johann Wolfgang Doebereiner discovered the high light sensitivity of iron oxide and manganese oxide when combined with oxalic acid.

1832: Dr. Gustav Suckow discovered that potassium bichromate becomes light-sensitive when mixed with an organic-substance.

1839. 13th April: Franz von Kobell, together with Carl August von Steinheil, presented to the Bayerische Akademie der Wissenschaften (Bavarian Academy of Science) paper negatives made in a cylindrical camera.

1839: Albrecht Breyer invented the reflex method of photographic copying of opaque originals without a camera.

1873: Hermann Wilhelm Vogel discovered optical sensitization. It was of fundamental importance both for correct tonal rendering in monochrome and in colour photography.

1891: Momme Andresen introduced the Rodinal developer on which many later developers are based.

1895: Wilhelm Conrad Röntgen discovered X-rays and invented radiography.

1901: Heinricus Lüppo-Cramer invented desensitization.

1903: Adolf Miethe and Arthur Traube discovered isocyanine dyes and introduced them into photographic practice. They are of special importance for colour sensitization and paved the way for the modern panchromatic plate.

1904: Otto Perutz succeeded in preparing the first panchromatic emulsion to incorporate a permanent colour sensitizer. Additional sensitizing dyes were introduced by Ernst König, Benno Homolka and other chemists at the Höchst dye factory.

1905: Adolf Tellkampf and Arthur Traube jointly invented the photographic tracing process known as "Fotoldruck".

1912 (1913, 1914): Dr. Rudolf Fischer took out basic patents for the subtractive colour process using intregal tripack film and paper, and involving colour development.

1917: Gustav Kögel invented the most widely used modern plan copying process—the Ozalid process.

1920: Henricus Lüppo-Cramer introduced desensitizers which made photographic development possible in relatively bright light.

1920: Robert Schuloff discovered the green sensitizer.

1936: Introduction of integral tripack colour process (Agfacolor) based on the work of Dr. Gustav Wilmanns and his associates, and using non-diffusing couplers.

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

1949: Introduction of document copying process, based on the work of Dr. Edith Weyde, giving a direct positive from the original by image diffusion.

Camera Developments. 1671: Athanasius Kircher, a Jesuit, improved the laterna magica.

1676: First portable reflex box camera obscura described by Johann Christoph Sturm, Nürnberg.

1685: Small box reflex cameras made by Johann Zahn.

1841: Peter Wilhelm Friedrich Voigtländer produced in Vienna the first daguerreotype camera made entirely of metal. He also founded the firm of Voigtländer in Braunschweig (1849).

1914: Oskar Barnack completed the first two models of the Leica camera.

1925: Introduction of the Leica camera, marking the beginning of the miniature era.

1928: Reinhold Heidecke introduced the Rolleiflex camera: the first precision twin-lens reflex.

1936: The first single lens miniature reflex camera, the Kine-Exakta, was constructed at the Ihagee Camera Works in Dresden.

Development of Optics. 1840: Peter Wilhelm Friedrich Voigtländer pioneered the production of the Petzval lens.

1865: Carl August von Steinheil, working with his son Adolf, manufactured the distortion-free, symmetrical Periskop lens; and in the following year Adolf Steinheil computed the Aplanat lens, which was free from distortion and dispersion.

1886: A glass technology laboratory was founded by Friedrich Otto Schott at the instigation of Ernst Abbe for the production of special glass for lens manufacture. This work laid the foundation of modern lens design. Abbe associated himself with Carl Zeiss' workshop and later produced the anastigmat lens invented by Paul Rudolph.

1889: Paul Rudolph computed an unsymmetrical anastigmat giving fine definition to the edge of the image. The Zeiss Protar and Tessar lenses were developed from this lens.

1893: Emil von Hoegh, in the firm of C. P. Goerz, constructed the first symmetrical (Goerz) double anastigmat lens, the Dagor.

1902: Christian Bruns and Friedrich Deckel constructed the Compound shutter.

1912: Friedrich Deckel devised the Compur shutter, the most universally used between-the-lens shutter in the world today.

1924: The Elmar, the first special anastigmat lens for the Leica, was computed by Professor Dr. Max Berek.

Other Developments. 1839: 25th February: the word Photographie was first used in the journal *Vossische Zeitung* by Johann von Maedler.

1882: Georg Meisenbach introduced the direct reproduction of half-tone images by means of a cross-line screen. Meisenbach's Autotypie was the first photographic half-tone process used commercially in book printing.

1925: Dr. Vielkämper introduced the safe and smokeless vacuum flash bulb with tin foil for electric ignition.

Industry. The German photographic industry is almost as old as photography itself. As soon as the necessity for the manufacture of photographic products arose, existing plants and laboratories took up the work and increased their sphere of activity.

The following dates denote the origin of a number of firms whose activities reflect practically the whole German photographic development.

Voigtländer & Sohn (founded in Vienna in 1756), in Braunschweig since 1849—lenses, cameras.

Dr. Carl Schleussner, Frankfurt-on-Main (since 1830), supplied raw materials for the wet collodion process in 1860.

C. A. Steinheil, Munich (since 1837)—lenses.

Carl Zeiss, Jena (since 1846)—lenses.

E. Schering, Berlin (since 1851) began the production of photographic chemicals in 1854.

Eduard Liesegang, Düsseldorf (since 1854)—projectors, enlargers and photographic papers.

Trapp & Münch, Friedberg, Hessen (since 1861) produced photographic salts and albumen papers.

Zeiss-Ikon (a merger of the firms of Zeiss, Ika, Ernemann, Contessa, Nettel, Goerz), formerly in Dresden, now in Stuttgart and Kiel, traces its origin back to Richard Hüttig's camera workshop in Berlin in 1862—lenses, cameras.

Ernst Leitz, Wetzlar, was founded by Carl Kellner and taken over by Ernst Leitz, sen. in 1869, the name being changed at the same time by the new owner—lenses, cameras, microscopes.

C. P. Goerz, Berlin (since 1886)—lenses. After the first World War the firm passed into the hands of Carl Zeiss, Jena.

Agfa Aktiengesellschaft für Anilinfabrikation was established in 1867 and began production of photographic developers in 1889.

Mimosa, A. G., formerly in Dresden, now in Kiel, was founded in 1889 in Cologne-Ehrenfeld—photographic materials.

Industry and the World Wars. Except for a monopoly of the production and supply of sensitizing dye stuffs, the German photographic industry before 1914 developed on similar lines to that of other European countries. After the First World War, in spite of the confiscation of many patents and the losses resulting from the economic collapse, German industry made a remarkable recovery for the following reasons:

(1) Manufacturers had to look for new products and markets. Big firms incorporated old crafts and hand-made goods to be manufactured on industrial mass-production lines.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

(2) New inventions were exploited for this drive (miniature camera, flash bulbs).

(3) The industry publicized photography on a scale not previously attempted in Europe.

The Second World War ended all this and the industry, in addition to suffering considerable damage, was afterwards divided into two parts, one in the Deutsche Bundesrepublik (German Federal Republic, West Germany) and the other in Deutsche Demokratische Republik (German Democratic Republic, East Germany).

WEST GERMANY

Reconstruction began at once in the Federal Republic. In the first ten post-war years its photographic industry again became stable and successful. Three important factors were:

(1) The revival of the Verband der Deutschen Photographischen Industrie e.V. (German Photographic Manufacturers' Association) in Frankfurt in 1946 and its intelligent and energetic leadership.

(2) The initiation of Photokina, the International Photo and Cine Exhibition, Cologne, which in 1950 for the first time displayed to visitors from all over the world the new German photographic products and their applications. From 1951 Photokina became international both in its trade fair and its cultural section. It is now recognized as the most important exhibition of photographic products and activities in the field of photography. The 1963 Photokina attracted 619 industrial exhibitors from 22 countries, and many more nations contributed to the picture exhibitions. The fair occupied 760,000 square feet in nine halls and there were more than 202,000 visitors during the ten days of opening.

(3) The foundation of the Gesellschaft zur Förderung der Photographie e.V. (Society for the Advancement of Photography), Frankfurt, an organization financed voluntarily and jointly by industry and dealers. It has created a centre supplying the press, free of charge, with articles on photography and good pictures, it runs a general advertising campaign for the benefit of photography, and engages in many other promotional activities.

There are over 10,000 retailers in the German Federal Republic (West Germany) and their interests are represented by Deutscher Photo- und Kinohändler-Bund (German Photographic Dealers Association) at Hamburg. Besides the usual photographic supplies and processing services, many dealers run their own lectures and instruction courses. A 1962 survey revealed that 16 million adults in West Germany are camera owners.

Societies and Clubs. The leading German photographic society is the Deutsche Gesellschaft für Photographie e.V. (The Photographic Society of Germany) in Cologne. Membership is by invitation only, and it is for persons who have distinguished themselves in the service, and furthered the progress, of photography. The Society organizes international congresses and awards an annual prize for cultural achievement in photography (which includes a sum of D.M. 10,000).

The top practising photographers are organized in the Gesellschaft Deutscher Lichtbildner (Society of German Photographers). Members must submit work for each annual exhibition. The bulk of the professional photographers is embraced by Centralverband des Deutschen Photographenhandwerks (Federal Association of the Photographic Craft) counting about 6,000 members.

Press and magazine photographers are organized in the Deutscher Journalistenverband (German Journalists' Association) at Bonn.

The amateur clubs—about 550—are federated to the Verband Deutscher Amateurphotographen-Vereine e.V. (Association of German Amateur Photographic Clubs) which in its turn is affiliated to the Fédération Internationale de l'Art Photographique.

Schools. The leading school of photography, the Höhere Fachschule für Photographie (High School for Photography) was built and opened in Cologne in 1954. It is sponsored and financed jointly by the State North-Rhine-Westphalia, the City of Cologne, the photographic industry and trade. It enjoys the reputation of being the best equipped place for studying and practising photography. It has three sections, one for instructing dealers and dealers' employees, one for creative and colour work and one for research. It covers 45,000 square feet and occupies six floors.

Four more schools, Bayerische Staatslehranstalt für Lichtbildwesen (Bavarian State School of Photographic Arts) in Munich, Folkwangschule (Folkwang-School), in Essen, Staatliche Hochschule für Bildende Künste (State School for Art) in Hamburg and Letteschule (Lette School) in Berlin endeavour to educate pupils mainly in the creative side of photography. There are also a number of private schools, many of which specialize either in particular techniques—e.g., colour—or follow definite artistic trends. The Faschschule des Deutschen Photo- und Kinohandels (School of the German Photo- and Cine Trade), founded 1957 in Kiel, is organized by the Dealers Association and controlled by the Ministry of Culture of Schleswig-Holstein. In three yearly courses it teaches technical chemical and sales knowledge to dealers' employees.

Publications. Since the early days of photography a firm in Halle has published a wide range of standard works of scientific and artistic value intended both for professional and amateur photographers. This firm now publishes in Düsseldorf the monthly magazine *Foto Prisma* for professionals and *Foto Rundschau* for amateurs. A Munich Company which

specializes in the publication of photographic books is also responsible for *Foto Magazin*, the largest German amateur photographic magazine, and the dealers' magazine *Der Fotohändler*.

CC-0. Ameriqam Digital Preservation Foundation, Chandigarh

The official organ of the photographic dealers, Inpho, is published in Düsseldorf. A more technical magazine, MFM (Monatliche Fototechnische Mitteilungen), is published in Ludwigsburg, and the weekly Photo-Presse, published in Hannoversch-Münden, serves the interests of the professional photographer.

A Berlin publishing house specializing in periodicals for the radio, photographic and motion picture industries, publishes the monthly magazine *Photo-Technik und Wirtschaft*, dealing mainly with industrial and trade matters. In Stuttgart, Dr. Wolf Strache revived in 1955 the famous pre-war yearbook *Das Deutsche Lichtbild*.

Dr. Erich Stenger of Kreuzwertheim-am-Main was responsible for an important scientific and historical collection, which bears his name and which, after his death in 1957, was bought by the Agfa Works in Leverkusen. In 1963 the Stadt (City) Museum of Munich took over the large photographic (mainly optical), collection of Dr. Rudolf Loher, opening the first photographic museum in West Germany.

Artistic Trends. The first important exhibition aimed at raising the level of pictorial photography was organized in Hamburg in 1893 by Ernst Juhl and Alfred Lichtwark. The principal participating photographers were Rudolf Dührkoop of Hamburg, Nicola Perscheid of Berlin, Wilhelm Weimer of Darmstadt, and Hugo Erfurth of Dresden, later Cologne. Another outstanding international exhibition was staged at Dresden in 1909.

After the First World War two main trends developed, both of which had a profound influence on photography everywhere.

One was the abstract movement, derived from the famous Bauhaus in Dessau, later Weimar, which became the pioneering centre of modern art where photography was recognized and encouraged as a means of artistic expression. Well known personalities from many lands—e.g., the Hungarian, Laszlo Moholy-Nagy, and the Austrian, Herbert Bayer—were attracted to the Bauhaus, worked there, and carried the Bauhaus spirit abroad. The use of photography for publicity, as in posters, murals and book-covers, was one of the particular achievements of the Bauhaus Group. The outstanding event of the period was the exhibition *Film und Photo*, Stuttgart, 1929.

A typical lone worker of the same period was Albert Renger-Patzsch who specialized in the portrayal of simple objects, hitherto overlooked by photographers, often in a new large close-up treatment. His rendering of these objects came to be known as the Neue Sachlichkeit (New Objectivity) and it revealed both the abstract and the factual beauty of our everyday surroundings.

Another factor was the rise of photojournalism. In this the publishing house of Ullstein, Berlin, with the magazines *Berliner Illustrirte*, *Uhu* and *Die Dame* paved the way for photo journalism as we know it today. Dr. Erich Salomon was a singularly outstanding photographer in the field of candid photography and his remarkable studies of political personalities, taken with inferior materials and the available light without the victim's knowledge, introduced a new era in photographic reporting. Many other photographers who have since achieved world fame, such as Alfred Eisenstaedt, first obtained recognition through their work for Ullstein. Leading illustrated magazines the world over owe much to the ideas and initiative of these German photographers and publishers.

Dr. Paul Wolff did much to rescue photography from stiff formality in his pioneer use of the miniature camera for his dynamic and unorthodox pictures. His work inspired amateurs and professionals alike to look at people and the world around from a new angle.

The main aim of photographers in West Germany since the war has been to catch up with the progress made in the western world during the pre-war years, to learn to use new equipment and techniques—e.g., electronic flash—and to resume the experimental work of the period between the wars—e.g., abstract and impressionist trends like "fotoform" and "subjektive fotografie" but with a modern approach.

A most hopeful proof of the new vision of modern times has been afforded by the Arbeitsgemeinschaft Jugend Photographiert exhibitions, organized by Photokina since 1954. Photographs selected from many thousands of entries have shown that the German Federal Republic is again contributing greatly in the field of creative photography. From the prizewinners have emerged a new crop of professionals. Many of these are photo-journalists, who have founded an international group known as European Magazine Photographers, to which nationals of other European countries are also invited.

The West German Government established in 1961 an annual Youth Photo Prize, the sum of DM. 10,000 being presented to the winning pictures. L.F.G.

Industry Today. The West German photographic industry is one of the oldest established and most highly developed in Europe. Its primary interest has traditionally been in the manufacture of equipment, in particular high quality cameras and lenses, although in recent years the production of sensitized materials has come to gain an important place.

There are at present 157 establishments undertaking the manufacture of photographic goods, together providing employment for

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

approximately 50,000 persons, and these are located principally in the southern part of the country, leading centres of production being Stuttgart and Munich. Of the total number of establishments, 141 with about 38,000 employees are concerned with equipment production whilst the remaining 16 establishments and 12,000 work people undertake the manufacture of sensitized goods and chemicals.

The most important single manufacturer is Agfa-Gevaert, A.G., a subsidiary of the industrial combine Farbenfabriken Bayer, which has about 11,000 employees and a turnover of DM. 425 million in 1962. This company produces still and cine equipment and a wide range of sensitized materials, and its output of still cameras was announced to have reached one million units per annum in 1963.

In addition to Agfa, the largest companies in the equipment field are Franke & Heidecke ("Rollei" trade mark), Kodak, Leitz, Voigtlander, and Zeiss Ikon, being together responsible for almost the entire industry's output of still cameras. Among these, Kodak specialize in the production of 35 mm. still cameras, having 2,050 employees and a turnover in 1963 of DM. 135 million, whilst Zeiss Ikon are well known in the sphere of optical goods in addition to the manufacture of miniature cameras and lenses, with some 5,300 employees and a turnover of DM. 100 million in 1963.

The sensitized materials sector is headed by Agfa, with Perutz (also controlled by Farbenfabriken Bayer) as the second largest photochemical producer, making all types of film, plates and chemicals, having some 1,500 employees. The formerly independent Agfa Company merged with the major Belgian producer, Gevaert, during 1964 to form the largest photographic manufacturing group in Europe. The combined annual turnover in 1963 was about £108 million sterling.

Another important manufacturer of sensitized products is Schleussner ("Adox" trade mark), which also produces still cameras and projectors, with about 2,000 employees. This company has now become a fully owned subsidiary of DuPont, the leading United States chemical producer.

There are four trade associations, membership of which is voluntary, covering between them practically the whole equipment and photo-chemical sectors of the industry. The principal organizations are the Verband der Deutschen Feinmechanischen und Optischen Industrie and the Verband der Deutschen Photographischen Industrie, which represent the interests of photographic apparatus manufacturers with regard to all trade matters.

An important influence on the development of the industry has been the Photokina, an international trade fair started in 1950 and held thereafter at varying intervals in Cologne, which forms a focal point for new ideas and products.

Production. The production of photographic goods has shown a steady growth in output during the last five years, although since 1960 the effects of Japanese competition in the important field of still cameras has been reflected in reduced production and exports. The industry also undertakes the manufacture of a wide variety of accessories and lenses, whilst the output of cine equipment, which has hitherto been relatively small in keeping with the domestic market for such products, is now being expanded to provide increased supplies in the future.

All types of sensitized materials are produced, the output of which has risen considerably in volume since 1959, and this group now accounts for about two-fifths of the total value of photographic goods production. Important items are sensitized paper and roll film, both of these having expanded noticeably during the period.

Imports. The value of imported photographic products has recorded a substantial gain during the last five years, reaching a total of DM. 193·6 million in 1963, of which approximately a half was composed of sensitized materials and chemicals.

Among apparatus, imports of still cameras have more than trebled in value during the period, the bulk of these being accounted for by the amateur type. In 1963 supplies came principally from Japan, with DM. 4·0 million, and the U.S.A. with DM. 5·7 million's worth.

The largest item, cine equipment, has shown an impressive rise in value to DM. 17·9 million in 1963, of which DM. 15·1 million was composed of 8 mm. cameras and projectors. The main sources of the latter were Japan (DM. 7·3 million), and Switzerland (DM. 4·0 million).

Sensitized material imports have increased considerably in value between 1959 and 1963, reaching DM. 102·2 million in the latter year. The greatest expansion has occurred among sensitized paper, imports of which have nearly trebled in value to DM. 18·7 million, due mainly to increased imports from Belgium, which supplied DM. 12·0 million's worth in 1963. The leading product throughout the period has been roll and cine film, together totalling DM. 46·1 million in 1963, the principal sources of supply being Belgium (DM. 10·1 million), Italy (DM. 10·2 million), and the U.S.A. (DM. 11·5 million). Belgium is also the main supplier of plates, X-ray, and sheet film, with DM. 16·7 million's worth out of the 1963 total imports of DM. 32·9 million.

Exports. A more moderate rate of increase than among imports has been shown by exported photographic equipment and materials, although their value is more than treble that of the former. Of the DM. 650·1 million total value of exports in 1963, the largest share was accounted for by apparatus, in particular still cameras, the exports of which rose to a peak in 1960 but have since declined somewhat with

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the growing competition of Japanese producers in world markets. The largest single customer is the United States, whilst the other E.E.C. members and the E.F.T.A. countries are important markets.

Still projectors, enlargers and reducers together comprise the next most important item exported, with a total value of DM. 65·3 million in 1963, of which Switzerland received DM. 7·1 million, Sweden DM. 8·3 million, and the U.K. DM. 6·0 million's worth. Exports of cine cameras and projectors have shown little growth in value during the last five years, although in 1963 8 mm. equipment production started to expand and should be reflected by increased exports in the future. This type accounted in 1963 for DM. 23·3 million of the DM. 42·5 million total, a major customer for which the U.S.A. taking DM. 4·5 millions' worth during the year.

Sensitized material exports have risen by 75 per cent in value since 1959 to reach DM. 221·1 million in 1963. Among the leading products is photographic paper, totalling DM. 93·2 million during the year, the chief destinations of which were the U.S.A. (DM. 11·1 million), Italy (DM. 8·3 million), and France (DM. 6·2 million).

Roll and cine film are also leading products, together accounting for DM. 85·1 million in 1963, of which Switzerland received DM. 8·5 million and the U.S.A. DM. 5·5 million, whilst exports of plates, X-ray, and sheet film have trebled in value since 1959 to reach DM. 28·8 million, France receiving DM. 4·6 million's worth.

EAST GERMANY

Organizations. Professional photographers are organized in the appropriate sections of the Handwerkskammer (Chamber of Crafts) and the Verband der Deutschen Journalisten (Union of German Journalists). Young amateurs join the photographic association of their school, youth club or the youth group at their place of work. Older amateurs can join photo-groups sponsored by their Trade Unions or clubs of the Deutsche Kulturbund (German Cultural Federation). There is an elected leadership for all groups, circles and clubs in the Zentrale Kommission Fotografie—ZKF (Central Photographic Commission), an organ of the Deutsche Kulturbund, with sections for colour photography, youth photography, exhibitions, tuition, etc. The ZKF represents East German amateurs in working with societies from other countries and with international bodies. Branch organizations of the ZKF, known as Bezirks-und Kreiskommissionen für Fotografie (Local Commissions for Photography), are found in various districts; their leadership is elected. In these districts, there are regular courses of instruction. A postal study course keeps the group leaders up-to-date in their photographic and instructional knowledge.

Characteristic of East German organizations is the close co-operation between amateurs, professional photographers and photo-journalists in the running of the various commissions, courses and groups. This is why there is no need for special photographic societies.

The ZKF has established an archive of the best photographs by East German photographers, and also runs the Museum für Fotografie (Museum for Photography) in Dresden; it publishes the periodical *Fotografie*.

Exhibitions. There is a widespread and lively interest in picture exhibitions. In schools, clubs, firms and neighbourhood areas, there are often small exhibitions of defined subject content to which anyone can contribute. Besides these, there are annual or biennial progress shows of the best pictures in black-and-white and colour. Societies from other parts of the country are invited to submit work for consideration in these. Every other year, the Deutsche Fotoschau (German Photo Show), and every third year the Berliner Internationale Fotoausstellung —Bifota (Berlin International Photo Exhibition), take place. In 1962, nearly 10,000 photographs were contributed to the latter from forty-one countries.

Newspapers, periodicals and social organizations often hold photographic competitions, the results of which either go on exhibition or are published.

Schools. Besides an engineering school (Ingenieurschule für Feinwerktechnik) in Jena, in which photographic and other subjects are covered, and the Deutschen Hochschule für Filmkunst (German High School for Cinema Art) in Berlin-Babelsberg, there is a specific training centre for photography in Leipzig. This has grown from the Fachschule für fotomechanische Vervielfaltigungsverfahren (Trade College for Photomechanical Processes) founded in 1893 at the then Leipziger Kunstakademie (Leipzig Academy of Art). Since 1945, the Abteilung Fotografik at the College der Hochschule für Grafik und Buchkunst (Department of Photographic Design at the College of Graphic and Printing Arts) had been operating a five year course leading to a final diploma (Hochabschluss). This course provides training in photography as an art form and its application in conjunction with typography and design in, for example, lay-out, poster work, publicity, advertising and in illustrated periodicals. Since 1963, this department has also run a three year specialist class for applied photography.

Publications. The most important photographic publications are issued by the Fachbuchverlag, Leipzig, which absorbed the former VEB Fotokinoverlag, Halle. The latter, with 125

CC-0. Jangamwadi Math Collection. Digitized by eGangotri

years of publishing history behind it, publishes about thirty different photographic books annually, as well as the monthly periodicals *Fotografie* and *Fotokino-Magazin* (Phot-Cine Magazine), the former on the advanced, the latter at beginners' level. The press is also responsible for the export magazine *Jenaer* Rundschau (Jena Review). A Berlin publisher caters for still and cine amateurs with technical leanings through its monthly *Bild und Ton* (*Picture and Sound*). Scientific, medical and other fields of applications are being covered by several publishers specializing in the subjects in question. Furthermore, nearly every firm in the photographic industry produces its own detailed information sheets.

Trends. The overriding significance of photography lies in its pre-eminence as a medium of pictorial communication, aesthetic reflection of reality and expression of human experience.

East German photographers accept an obligation towards those traditions and pioneers of photography who were particularly concerned with human dignity and the beauty of environment. They made their own contributions to photographic history by research into the long neglected area of working class photography. The social criticism and evidence of these pictures about the life of workers set a pattern for a human, committed and positive photographic outlook. This outlook is opposed to formal experiments, abstraction and decadence, which are looked upon as emotional negations and anxiety in the face of realities, reflecting distortion of human values. Reaching beyond the preoccupation with the formal elements of picture making, there is a search for picture content that will reflect human ideals as defined by the country's social order with an emphasis on peace and international understanding.

Interest is centred in three areas: colour photography, which is predominantly used as a reversal process; the camera work applied to photographic journalism, which is also accessible to amateurs, who are often concerned with the pictorial documentation of their local and industrial environment; and youth photography, which is sponsored by the youth movement and the schools alike (50 per cent of all schools have their own photographic work groups).

Industry. The optical industry and camera works, centred in Jena and Dresden, were largely destroyed during the war, but have since been reconstructed under public ownership. The old works were considerably enlarged and expanded in line with national economic planning.

East Germany specializes today above all in making quality single lens reflex cameras, interchangeable lenses, and apparatus for scientific photography and laboratory technology. Besides a number of old established but continually developed makes, various automatic cameras have also been designed, and all kinds of photographic accessories (exposure meters, projectors, flash apparatus and so forth) and cameras in the middle and lower price brackets (especially for beginners' photography) have come into production. In keeping with growing needs, there has been considerable increase in the production of films and chemicals since 1945.

Products are sold in specialist state-run and private shops, which offer a great deal of service to customers. Photographic goods may also be obtained through mail order houses.

The East German photographic industry exhibits annually at the Leipzig Fairs and in a special Fair, devoted to film, radio, photography and television in Dresden. Export is handled by a state organization through agencies in most countries. The whole photographic industry is of particular export importance to East Germany. A.N. & B.B.

Production. During 1963 the output of photographic equipment and materials has shown a small overall increase, although production of several times within the total has remained static or fallen off. The East German industry has clearly not succeeded in maintaining its growth of the previous year, due most probably to labour shortages and other economic difficulties in the country.

Still cameras continued to be the most important products among apparatus, and provided the only increases during the year. The output of reflex cameras gained 14·1 per cent in quantity, compared with only 2·3 per cent in 1962, to reach the highest figure yet attained with 139,600 units. Production of miniature types, although rising by 10 per cent to 192,900 units, showed a slackening in the growth of nearly 30 per cent achieved during the previous year and output has not yet regained the level reached in 1960. Other equipment almost exactly reversed its gain of 1962 with a fall of 13·3 per cent to 187,200 units.

The value of photocopy apparatus produced in 1963 dropped further to DM 56·8 million, whilst other equipment and parts showed a small fall to DM 25·1 million in contrast with its previously rising value.

Sensitized material output, excluding film base, rose by 2·5 per cent to a total of 27·6 million square metres in 1963, compared with an increase of 5 per cent a year earlier.

The leading product continued to be sensitized paper, which showed a slightly increased rate of growth with a rise of 4·6 per cent to reach 11·5 million square metres. The output of negative still and cine film of both black-and-white and colour types, however, remained unchanged at the 1962 level.

Production of positive cine film achieved a rise overall from 13·4 to 13·6 million square metres, whilst altering in composition. Black-and-white stock again increased slightly during

EAST GERMAN EXPORTS OF PHOTOGRAPHIC EQUIPMENT

Thousand Units

	1959	1960	1961	1962	1963
Reflex cameras	84·5	99·0	83·0	80·9	82·3
Other equipment	161·3	175·0	159·7	148·3	133·5
Total	245·8	274·0	242·7	229·2	215·8

EAST GERMAN EXPORTS OF SENSITIZED MATERIAL

	1959	1960	1961	1962	1963
Film base	706	468	640	632	340
Sensitized paper	2,931	2,517	3,109	2,508	2,553
Still and cine film:					
Black and white	8,812	7,858	9,948	9,435	10,006
Colour	3,676	3,456	3,398	3,045	2,749
Total paper and film	15,419	13,831	16,455	14,988	15,308

the year, and now accounts for nearly 80 per cent of the group's total, but the production of colour material declined noticeably.

The output of raw film base rose to a smaller extent than in 1962 to reach 27·8 million square metres, practically all of which was taken by the domestic market.

Exports. East German exports of photographic equipment continued their overall decline during 1963, although reflex cameras showed a marginal increase to 82,300 units. Since the destination of exports is not shown in the trade returns it is difficult to know where changes have occurred, but some information can be gathered from other countries' import statistics. Thus, in 1963 the U.K. received 23,900 still cameras from East German producers, compared with 15,200 units during the previous year, the bulk of these in both cases being composed of miniature models. Still cameras imported by Yugoslavia, however, fell heavily from 15,200 to 4,300 units over the same period, whilst Hong Kong purchases rose slightly from 1,800 to 2,600 units.

Exports of sensitized materials (excluding film base) totalled 15·3 million square metres in 1963, a rise of 2·1 per cent from 1962 contrasting with a fall of almost one-tenth which took place in the latter year. Both sensitized paper and black-and-white still and cine film contributed to this increase, but colour still and cine stock dropped by 9·7 per cent in volume to continue its decline of recent years. Raw film base exports also fell off in 1963.

The leading market for all types of film is the U.S.S.R., whilst other important purchasers include Eastern Bloc members, India, and Hong Kong.

GEVAERT, LIÉVIN, 1868–1935. Belgian photographer. Founder (1890) of the N.V. Gevaert Photo-Producten works in Antwerp. Gevaert manufactured originally photographic papers but soon started manufacture of all types of film.

GHOST. Gratuitous image of a light source formed by double reflection between the internal surfaces of the front and back components of a lens. Ghost images are troublesome if they are sharp, and lens designers try to arrange matters so that they will be diffused over the whole focal plane and therefore less obvious. Most lenses produce ghost images if a brilliant light source is included in the field of view.

Such images are a particular kind of flare spot in the form of an actual image, generally distorted, of the light source. A window will often appear as a ghost image in an interior, or a bright patch of sky in an outdoor scene. The ghost is usually inverted and occurs on the opposite side of the picture to the true image.

See also: *Coated lens; Flare; Faults; Halation; Irradiation.*

GHOST PHOTOGRAPH. Trick effect produced by making two exposures of the same scene on the same plate. The first exposure is made of the empty scene, and the second with someone present—e.g., sitting in a chair. The print shows the sitter as a transparent figure through which the background can be seen.

It is equally effective, and sometimes more convenient to photograph the person against a dead black background and then make a normal exposure on the same plate of the scene in which the ghost is to appear. In this case the position of the ghost must be marked on the focusing screen so that it can be correctly placed in its setting in the second exposure.

The same technique can be used with a cine camera to produce a moving picture of a ghost.

GIANT ENLARGEMENT. The following procedure is reasonably adequate for the production of the occasional large (but not too large) print. As a means of producing giant enlargements in variety and quantity, however, both the equipment and the procedure would be unsuitable. There is very little standard equipment available that measures up to the requirements of the professional maker of large prints. Enlargers, processing tanks, etc., must of necessity be purpose-designed and purpose-made.

A correctly exposed and developed negative should enlarge up to twenty diameters without too serious a loss of resolution. To produce prints of this proportion involves no basic departure from normal enlarging technique. The main consideration is that of equipment—what new equipment must be obtained and how best to modify and use existing equipment, particularly in relation to the space available.

The mounting of the enlarger lens, as well as the control of parallelism of negative holder, lens panel, and projection board, must be done carefully and accurately.

Enlarger. When considering the enlarger it is important to remember that the light source will be much farther away than usual from the printing base. A light source of the double condenser type makes focusing easier, minimizes loss of contrast and cuts down the length of exposure.

Where there is enough working space the ideal instrument is undoubtedly the horizontal enlarger. Few models are now made, but second-hand ones can be obtained and are relatively inexpensive. A second-hand quarter-plate or half-plate field camera will serve very well as the basic component of a home-made horizontal enlarger.

It is possible to convert some vertical enlargers to horizontal operation. In a number of instances the lamphouse assembly can be swung and locked in the horizontal position, and there is also available a prismatic attachment that fits on to the enlarger lens and throws an image at right angles to it. In other instances the lamphouse assembly can be completely detached and secured in a home-made horizontal cradle.

It is possible, however, on many vertical enlargers to throw a larger-than-normal image

HIGH ENLARGER MAGNIFICATIONS. Top left: *Right-angle projection via a 45° mirror in front of the lens.* Top right: *Swinging the lamp house through 90°. In both cases the paper is pinned to a suitable wall.* Bottom: *Projecting on to the floor*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

vertically by mounting the lamphouse assembly on the outside of the column and projecting the image over the edge of the bench on to the floor. The baseboard must be securely weighted down—e.g., with a pile of books.

Equipment. Outsize dishes are not essential. Three dishes, 16 × 20 ins. can be used to develop, rinse and fix prints of a considerably larger size. An ordinary domestic bath, provided the water is changed frequently, will serve very well as a washing tank.

Bromide and chloro-bromide paper can be bought in rolls in two standard widths, 20 ins. and 40 ins., the normal length being 25 feet.

The following items will be needed for cutting the paper:

(1) A sharp-pointed, short-bladed knife.

(2) A metal or hardwood straightedge.

(3) A strip of hard, smooth material (sheet metal, sheet plastic or glass) as a cutting base.

Because it is packed in a tight roll the paper will retain a spring-like curl until it has been well immersed in developer. The normal masking frame, therefore, besides being too small, would be inadequate to hold the paper firmly in position. It can best be secured to the base by darkroom pins.

Printing. The printing of giant enlargements calls for no departure from the normal procedure in the preparation of negatives. However, greater care than usual must be taken to keep negatives free from dust, scratches and other blemishes. Proper attention to cleanliness in processing can save hours of afterwork on the print.

In the following outline of print-making technique it will be assumed that the object is to produce an enlargement 20 × 30 ins.

Cut off a strip of paper from a 20 ins. roll and make the normal exposure test.

Cut a 32 ins. length of paper off the roll. Pin this length into position along the two 20 ins. edges. Do the same along the 32 ins. edges without piercing the paper—i.e., so that only the head of the pin presses down on it.

The scale of enlargement required will make a long exposure time necessary. For this reason, the strongest illumination that can be safely used should be fitted in the enlarger.

The considerable loss of contrast due to distance of projection when making a large print from a comparatively small negative makes necessary the use of high-contrast emulsions, which generally means results which are not of the highest possible quality. The professional avoids this difficulty by making from the original negative a near-perfect "reproduction print", using normal dodging and printing-in techniques. This print should be rich in detail in all tones (i.e. not too contrasty) as it will be copied to make a negative of suitable size, density, and contrast from which the ultimate enlargement will then be made.

Instead of thus making a copy negative, it is possible to use a pre-solarized film of a type supplied by a number of leading manufacturers. This material enables the production of a negative directly from a negative. By using an enlarger, printing control is still possible and the negative can be made to the required size, as before.

Processing. When the paper has been unpinned after exposure, it will spring back into a tightly-wound scroll 20 ins. in length.

Grasp the centre of the scroll with one hand and with the other slacken off about 12 ins. of paper, holding it tautly away from the scroll.

Feed the leading edge of the paper into the 20 ins. side of the developing dish. Press it firmly to the bottom and make sure it is quickly immersed by vigorous movements of the hand from side to side. Slacken off a further length of paper and repeat the process, while at the same time rolling up the paper from the leading edge until the whole area of paper has been drawn through the developer and thoroughly immersed.

Continue coiling and uncoiling the paper, first from one end and then from the other, until development is complete.

The print will now have become limp and easy to handle. Fold it in half, emulsion outwards (making sure it does not crease), rinse it in a water stop bath, then transfer it to the fixing bath.

To avoid uneven development it is essential to carry out the initial immersion in developer as quickly as possible. The beginner may find it easier to soak the paper in water after exposure until it is limp and easy to handle. The paper should then be wound once again into a scroll, drained, and fed into the developer by the method already described. If the final print consists of two or more separate pieces, exposed either in a single projection or in several projections, the professional excludes visual judgement in developing the sections, relying entirely on time and temperature control.

The print, having been fixed and washed, should be secured to a line by clothes pegs and left to dry.

Prints which are made in sections should be dried in such a manner that each section undergoes identical conditions with the others. If hung up, they should all hang in the same way, so that any stretch in one occurs also to the others, to the same extent, and in the same direction.

When dry the print is trimmed to size and knifed and spotted. Particular care is given to spotting out the white marks left by the pin heads along the edge of the print. D.M.

GLAMOUR PHOTOGRAPHY. Whatever it means in other applications, the word "glamour" means to the photographer the result of certain tricks and devices deliberately employed to enhance the specifically physical qualities in the portrait of a beautiful woman. Most of these techniques originated in the motion picture studios. In most cases, the aim is frankly to create an appearance of refined sex appeal.

Sex appeal is basic to glamour, but so is refinement. Any suggestion of vulgarity in a picture, and all glamour is ruined.

Much trickery has been invented by photographers in recent years to accomplish the basic purpose of the glamour photo—to make the subject look more desirable. Most of the trickery involves sublimating the earthy elements of sex appeal, and translating them into classic or stylized terms and interpretations. The best glamour picture is always an idealization of feminine beauty as well as a subtle compliment to the feminine appeal of the subject.

Unless the subject is a flawless beauty, however, with features such as no artist could improve, the glamour photographer must do more than merely record his subject's beauty in specific detail. Instead, he may show very little which is specific, and let his picture consist of a few vivid impressions.

Glamour photography incorporates a number of specialized techniques to arrive at the desired effect. Here are the principal considerations.

(1) The model. The model must have at least the basis of glamour, in the form of either beauty or sex appeal, and the more obvious these qualities, the easier the task of creating a glamorous picture.

(2) The setting. Take the pictures against a glamorous background, perhaps suggesting a life of ease and wealth. Remember, the object is to make your sitter look desirable. The setting should have an intimate and inviting air. In the studio, such a setting can be suggested with a simple prop.

(3) The costume. Intimate garments such as nightdresses and negligees have the highest glamour potential for studio pictures, whereas bathing suits and other sports costumes are favoured for outdoor shooting.

(4) The pose. Try to show the best features of a girl's figure in silhouette, put special emphasis on a good bust line and on trim hips and legs; then pose her face to give a flattering view of her hair, lips and eyes.

(5) Expression. For the intimate studio glamour shot, the ideal expression requires the girl to look pleasantly approachable and is arrived at usually by experiment—e.g., she may be asked to try sly, seductive smiles, to part her lips invitingly, to think about something good to eat, to try sidelong glances or direct gazes. This is the most difficult aspect of glamour photography in the studio. Working outdoors with the model in play clothes, it is much easier. It is necessary simply to have her look happy and friendly, as if she were naturally full of fun—and the quality will be there.

(6) Lighting. All the standard techniques of lighting for portraiture and figure work can be well applied in glamour photography. Basically, the theory is to emphasize the subject's most interesting features with highlights, and to subdue or conceal her other features with shadows.

(7) Make-up. This is especially important for indoor glamour work. Make-up artfully applied can do much more than cover complexion defects: it can accomplish some of the same purpose as lighting, stressing the good features and subduing, or better still correcting, less pleasing features.

(8) Retouching. Here again, the main application is for indoor close-up studies. The retoucher can work magic on a portrait type of glamour shot, removing all defects in the complexion, adding highlights where they will do the most good, and generally rounding off even the bone structure of the model. Backgrounds also can be subdued if necessary. If the photographer lacks the skill to do the retouching personally, there are professional retouchers who will do the job for him.

(9) Diffusion. Here is a trick which anyone can apply quickly and easily to glamourize his subject.

Simply place a diffusion attachment in front of the lens when shooting the picture, or, if no such attachment is available, use a piece of black gauze. The effect is to show all the main lines of the picture with apparent clarity, while all the undesirable details (complexion defects, hair on arms, and wrinkles) are obscured. It is important to accomplish the diffusion in the camera, rather than in the enlarging process. Camera diffusion spreads the highlights and lightens the shadows; enlarger diffusion, on the other hand, spreads the black accents and shadow areas and degrades or greys the highlights.

(10) Use good taste. It is treacherous work to seek consciously to emphasize sex appeal and there is a constant danger that the picture may become offensive. Remember that, while the sitter may wish to appear glamorous and will co-operate to that end, she will certainly not thank the photographer for making her look cheap or vulgar.

GLARE. In a camera, non-image forming light which may originate from scattering at dust particles, scratches and damaged lens coatings, and from reflections at lens surfaces, the iris diaphragm and lens shoulders, etc. This light usually results in an overall fog, or veil, at the image plane, though in some cases ghosting of the bright parts of the image may occur. Fortunately the tolerances of veiling glare in a camera are much larger than in a visual optical system, since the image contrast can often be maintained by suitable adjustments during exposure and development. However steps must be taken to reduce glare so far as is possible. Since reflections at the iris diaphragm frequently account for a large proportion of glare, stopping down the aperture is not necessarily beneficial; thus it should be ensured that the diaphragm as well as the bellows, lens shoulders, etc. in a system are matt black in order to minimise reflectivity. Lens surfaces should be kept free from dust and protected from scratching. The most effective step towards the elimination of glare is the use of coated lenses, particularly in systems having several air-glass surfaces.

Outside the camera glare refers to the reflection of intense light into the camera lens from highly reflective surfaces (e.g. water, glass, etc.). In outdoor photography this glare is avoidable only by changing the camera viewpoint. With artificial light, repositioning the light source or sources helps.

In copying set-ups glare reflected from the surface of the original being copied (even if not shiny) may reach the lens and produce a "hot spot", i.e. specially dense image patch on the negative. The remedy is correct setting up of the lamps at a suitable angle.

See also: *Coated lens; Document copying.*

GLASS. Transparent brittle substance made by the fusion of certain silicates. Physically it is a supercooled liquid, with no regular solid structure such as a crystal lattice. Different mixtures of various metallic silicates produce glasses of different optical properties. Apart from its use for the manufacture of lenses, glass is used in photography as a support for negative and positive emulsions (plates and slides), for glazing printing and picture frames, and for graduates, processing dishes, tanks, funnels and bottles for the various chemical solutions. Of the solutions that attack glass, hydrofluoric acid and certain of its salts are the only ones likely to be used by the photographer.

The greatest disadvantage of glass for articles in regular use is its brittle nature. A number of items of photographic glassware are nowadays made of a special hard glass similar to the familiar glass ovenware, but this material tends to make a clumsy, heavy article. For such purposes, plastics—in particular the flexible polythene varieties—are becoming increasingly used.

The hard surface of glass can be made to take an extremely high polish, however, and in this respect it probably has no equal at a competitive price. Because it gives a higher quality glaze than any other material, many photographers and a number of commercial printers use plate glass sheets for glazing prints in spite of its inconvenience.

See also: *Optical glass.*

GLASS (PHOTO-SENSITIVE). Glass containing certain heavy metal compounds can under exposure to ultra-violet radiation undergo an electronic modification of the metal ions. On subsequent heat treatment this leads to a change in the colour or the transparency of the exposed areas. In such glass it is therefore possible to produce photographic images. The first photo-sensitive glass of this kind was announced in 1947 in America.

There are three main kinds of photo-chemical action in glass: metallic image formation, non-metallic crystal formation and differential solubility.

Photo-sensitive glass for metallic image formation contains compounds of gold, silver, copper or palladium. It may also contain optical sensitizers such as cerium to extend the spectral absorption range; copper and silver act as their own sensitizers in this sense.

The glass is exposed through a normal black-and-white negative to ultra-violet rays between 3,000 and 3,500 A in wavelength, usually to a high intensity mercury vapour lamp or carbon arc. The sensitivity is very low, requiring exposures of the order of ten minutes. The image is formed throughout the depth of the glass with ultra violet rays of longer wavelength, but only in the surface if very shortwave radiations are used.

After exposure the image is developed by heating the glass to around 600°C. The image colour depends on the exposure and may vary from blue to brown, according to the metallic compound incorporated. Development takes about half an hour to one hour. The image itself is due to the conversion of the metal ions into sub-microscopic metal particles. Such images are virtually grainless and of very high resolving power. Cooling of the glass fixes the image which is then virtually permanent unless the glass is heated to its softening point again.

Photo-sensitive glass of this type is used for making graticules, photographic reproductions and photographically decorated glass ware.

In certain types of glass the metal particles produced by the exposure can act as nuclei for the growth of non-metallic crystals. The image then is an area of greater scattering power or opacity than the original glass itself.

Photo-sensitive glass with differential solubility yields a milky opalescent image after exposure and heat treatment. This image is preferentially soluble in glass etching solvents like hydrofluoric acid. Exposed and developed

Backgrounds also can be subdued if necessary. If the photographer lacks the skill to do the retouching personally, there are professional retouchers who will do the job for him.

(9) Diffusion. Here is a trick which anyone can apply quickly and easily to glamourize his subject.

Simply place a diffusion attachment in front of the lens when shooting the picture, or, if no such attachment is available, use a piece of black gauze. The effect is to show all the main lines of the picture with apparent clarity, while all the undesirable details (complexion defects, hair on arms, and wrinkles) are obscured. It is important to accomplish the diffusion in the camera, rather than in the enlarging process. Camera diffusion spreads the highlights and lightens the shadows; enlarger diffusion, on the other hand, spreads the black accents and shadow areas and degrades or greys the highlights.

(10) Use good taste. It is treacherous work to seek consciously to emphasize sex appeal and there is a constant danger that the picture may become offensive. Remember that, while the sitter may wish to appear glamorous and will co-operate to that end, she will certainly not thank the photographer for making her look cheap or vulgar. E.M.H.

GLARE. In a camera, non-image forming light which may originate from scattering at dust particles, scratches and damaged lens coatings, and from reflections at lens surfaces, the iris diaphragm and lens shoulders, etc. This light usually results in an overall fog, or veil, at the image plane, though in some cases ghosting of the bright parts of the image may occur. Fortunately the tolerances of veiling glare in a camera are much larger than in a visual optical system, since the image contrast can often be maintained by suitable adjustments during exposure and development. However steps must be taken to reduce glare so far as is possible. Since reflections at the iris diaphragm frequently account for a large proportion of glare, stopping down the aperture is not necessarily beneficial; thus it should be ensured that the diaphragm as well as the bellows, lens shoulders, etc. in a system are matt black in order to minimise reflectivity. Lens surfaces should be kept free from dust and protected from scratching. The most effective step towards the elimination of glare is the use of coated lenses, particularly in systems having several air-glass surfaces.

Outside the camera glare refers to the reflection of intense light into the camera lens from highly reflective surfaces (e.g. water, glass, etc.). In outdoor photography this glare is avoidable only by changing the camera viewpoint. With artificial light, repositioning the light source or sources helps.

In copying set-ups glare reflected from the surface of the original being copied (even if not shiny) may reach the lens and produce a "hot spot", i.e. specially dense image patch on the negative. The remedy is correct setting up of the lamps at a suitable angle.

GLASS. Transparent brittle substance made by the fusion of certain silicates. Physically it is a supercooled liquid, with no regular solid structure such as a crystal lattice. Different mixtures of various metallic silicates produce glasses of different optical properties. Apart from its use for the manufacture of lenses, glass is used in photography as a support for negative and positive emulsions (plates and slides), for glazing printing and picture frames, and for graduates, processing dishes, tanks, funnels and bottles for the various chemical solutions. Of the solutions that attack glass, hydrofluoric acid and certain of its salts are the only ones likely to be used by the photographer.

The greatest disadvantage of glass for articles in regular use is its brittle nature. A number of items of photographic glassware are nowadays made of a special hard glass similar to the familiar glass ovenware, but this material tends to make a clumsy, heavy article. For such purposes, plastics—in particular the flexible polythene varieties—are becoming increasingly used.

The hard surface of glass can be made to take an extremely high polish, however, and in this respect it probably has no equal at a competitive price. Because it gives a higher quality glaze than any other material, many photographers and a number of commercial printers use plate glass sheets for glazing prints in spite of its inconvenience.

See also: *Optical glass.*

GLASS (PHOTO-SENSITIVE). Glass containing certain heavy metal compounds can under exposure to ultra-violet radiation undergo an electronic modification of the metal ions. On subsequent heat treatment this leads to a change in the colour or the transparency of the exposed areas. In such glass it is therefore possible to produce photographic images. The first photo-sensitive glass of this kind was announced in 1947 in America.

There are three main kinds of photo-chemical action in glass: metallic image formation, non-metallic crystal formation and differential solubility.

Photo-sensitive glass for metallic image formation contains compounds of gold, silver, copper or palladium. It may also contain optical sensitizers such as cerium to extend the spectral absorption range; copper and silver act as their own sensitizers in this sense.

The glass is exposed through a normal black-and-white negative to ultra-violet rays between 3,000 and 3,500 A in wavelength, usually to a high intensity mercury vapour lamp or carbon arc. The sensitivity is very low, requiring exposures of the order of ten minutes. The image is formed throughout the depth of the glass with ultra violet rays of longer wavelength, but only in the surface if very shortwave radiations are used.

After exposure the image is developed by heating the glass to around 600°C. The image colour depends on the exposure and may vary from blue to brown, according to the metallic compound incorporated. Development takes about half an hour to one hour. The image itself is due to the conversion of the metal ions into sub-microscopic metal particles. Such images are virtually grainless and of very high resolving power. Cooling of the glass fixes the image which is then virtually permanent unless the glass is heated to its softening point again.

Photo-sensitive glass of this type is used for making graticules, photographic reproductions and photographically decorated glass ware.

In certain types of glass the metal particles produced by the exposure can act as nuclei for the growth of non-metallic crystals. The image then is an area of greater scattering power or opacity than the original glass itself.

Photo-sensitive glass with differential solubility yields a milky opalescent image after exposure and heat treatment. This image is preferentially soluble in glass etching solvents like hydrofluoric acid. Exposed and developed

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

areas of the glass etch up to fifty times faster than unexposed areas, leading to direct glass etching in depth. Such images are much sharper and more detailed than indirectly photo etched glass with a resist produced by conventional photographic methods. L.A.M.

GLASS PICTURES. Photographic images can be etched on glass by using a gum bichromate print as an intermediate. The process gives a "print" from a positive transparency, the image appearing as a positive when it is viewed against a dark background.

The Negative. Sized paper is first coated with a solution of one part each of gum arabic, sugar, and ammonium bichromate in eight parts of water and allowed to dry in the dark. The prepared paper is then exposed to daylight behind a positive transparency.

The sensitized layer of gum is hardened and made less sticky by the action of light, so, at the end of exposure, the areas behind the clear parts of the transparency are not as sticky as the areas behind the denser parts. While the surface is in this condition, it is dusted with fine bitumen powder; the powder sticks to the lightly-exposed areas more readily than to the heavily-exposed areas. The result is a direct positive of the transparency in bitumen dust on the sensitized paper.

This image is pressed into contact with the glass plate which has been previously warmed. The warmth softens the bitumen dust and makes it stick to the glass surface. When the paper support is soaked with water and peeled off, the bitumen powder is left and forms a positive image resist of the original transparency.

Etching. The glass is then exposed to the etching action of hydrofluoric vapour. Where the surface is protected by the bitumen dust, no etching takes place; elsewhere the glass is attacked by the acid and the result is a photographic image. The bitumen dust is finally washed off with petrol.

This is a reversal-negative process; the gum-bichromate-bitumen image being a reversal stage. The etched image is negative but acts as a positive since the dense areas scatter light and appear bright instead of dark. Hence the need for a positive original.

This method produces images which are an integral part of the glass. Image layers can be produced on top of the glass by any of the methods described for printing on metals.

Photographs may also be printed on a glass surface by any of the regular methods of printing on solid supports—i.e., the glass may be coated with a sensitized emulsion and printed under a negative by contact or enlarging; or it may have an image transferred to it by the transfer coating process; or it may take the place of the final support in the carbon or carbro processes.

Pictures in Glass. By an entirely different process photographic images can be formed inside the glass.

This process makes use of a special type of photosensitive glass containing colloidal silver or other metal in suspension. The glass is exposed through a negative to a strong source of ultra-violet light. This converts the colloidal metals in the glass into a form in which they can be precipitated and rendered visible. The actual precipitation is brought about by heating the glass to just below its annealing temperature. The result is a visible image embedded in the glass. L.A.M.

See also: *Printing on special supports; Stripping.*

GLASSWARE. Glass is a transparent material, therefore the shape of anything made of glass can only be clearly defined by lighting it so that it stands out as a dark shape against a light background or as a brightly lit shape against a dark background. With some subjects it is effective to combine both methods.

Silhouette Treatment. With the first type of lighting some of the sparkle of the glass may be lost but every detail of the shape will be perfectly clear. This is a great advantage if the photograph is to be reproduced. Glass most suitable for this treatment should be tall rather than squat—i.e., vases, decanters, jugs, etc.—and it should not have too much decoration.

LIGHTING GLASSWARE. Top: *Against light background lit by flood.* Centre: *Against black background with subject spot-lit.* Bottom: *Backlighting by sunlight streaming in through window; reflecting screen used on shadow side. The two camera positions yield a white and a black background respectively.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ETCHED GLASS IMAGES. To take an etched motif in a window, the back is evenly lit by several lamps, or one lamp moved into successive positions during the course of the exposure. The camera should point squarely at the window.

For this type of photograph the subject is placed, preferably on a plain surface or on a sheet of glass, near the edge farthest from the camera. This arrangement prevents the background line from cutting through the subject. A vertical white background, several feet behind the subject, is lit by spot or floodlight. No light is allowed to fall on the subject, therefore it stands out in silhouette. Variations in the background are sometimes made by casting shadows across it. This calls for care to avoid confusing the outline of the subject. For the same reason, textured backgrounds are avoided as they tend to give a false texture to the subject itself.

The best viewpoint for this type of photograph is nearly level with the base of the subject.

Highlight Treatment. It is more difficult to photograph glass so that it appears light against a dark background and the technique varies to some extent with the type of glass. Cut or engraved glass usually looks best against a dark background, more especially a plain surface that does not fight with the pattern on the subject. And it should curve upwards behind the subject so that there is no horizontal edge to cut the photograph in two. Tracing paper laid over a sheet of plate glass provides one suitable type of background as it enables the subject to be lit from below—a form of lighting which is often necessary.

The main modelling light is kept low and almost behind the subject. It is usually provided by a spotlight to ensure that light falls only on the subject, leaving the background in shadow. Where this light does not illuminate the subject sufficiently a second spotlight underneath the background is directed vertically upwards on to the subject; this light helps to outline such parts as the rim of a glass or vase or it may be used to pick up highlights in the base and stem. The viewpoint for this type of photograph can be anything up to 60° above the horizontal, but experienced workers tend to keep it lower.

Combined Silhouette and Highlight Treatment. A combination of light and dark background tones is usual with flatter subjects like ash-trays, shallow bowls and dishes. The subject is placed on a sheet of clear plate glass which is supported 3 or 4 feet above a plain white background. This white background is then lit by a spotlight adjusted until the areas of highlight and shadow look right when seen from the camera viewpoint. The final effect is that part of the subject is silhouetted against a light area, while parts like the rims and upper edges stand out as highlights against the shadow area of the background. A second light source above the plate glass is occasionally directed on to the subject itself to add extra highlights and sparkle.

Equipment. Really high class work for catalogue and "glossy" magazine reproduction is almost always done with a large format plate camera using a long focus lens stopped right down to give the necessary depth of field.

As with most commercial photography, a lens with a long focal length is generally chosen to avoid close-up distortion.

Normally, when photographing glass, best results are obtained from panchromatic material which helps to prevent excessive contrast in the negative. D.L.H.

GLAUBER'S SALT. Another name for sodium sulphate decahydrate. Used to prevent swelling of emulsions in hot weather processing.

GLAZERS AND GLAZING MACHINES. Prints may be glazed by using a glazing sheet on its own or in conjunction with a glazing machine. In the latter case, heat is applied to the glazing sheet to speed up the process.

For really large scale glazing where high speed is important, rotary glazers incorporating their own glazing surface may be used.

Glazing Sheets. Any smoothly polished, hard surface is suitable for glazing. Special sheets for glazing can be bought; these available are usually enamelled metal or chromium, the latter being more expensive but less likely to scratch easily.

Glass is a suitable substitute for a chromium glazing sheet, and it is almost universal opinion that plate glass will give a much better glaze than any other material; it does, however, need meticulous and regular polishing. Prints may even be glazed by squeegeeing them direct on to windows provided that the glass is perfectly smooth and clean.

Glazed tiles are suitable for glazing prints, although the surface of the tile must be free from cracks if a smooth glaze is to be obtained.

Glass and tiles are not suitable for use in a flat bed glazer where heat is applied. It is invariable practice to use chromium glazing sheets in machines.

Flat Bed Glazer. A flat bed glazer consists of a shallow metal box with a slightly curved top. This forms the bed of the glazer; it is heated by

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

FLAT BED GLAZER. The prints are squeegeed on the glazing sheet which in turn is heated from below. A fabric apron keeps the prints pressed against the sheet.

electric elements inside the box, the temperature being controlled by a switch and thermostat.

The bed is made to accommodate a standard-sized glazing sheet. An open frame carrying a pressure cloth of fabric is fastened over the bed so that the pressure cloth holds the glazing sheet in close contact with the top of the bed.

In use the heat is switched on while the wet prints are being squeegeed on to the glazing sheet. The glazing sheet is then laid on top of the bed and the pressure sheet is stretched over it and fastened down. After a period of 5 to 10 minutes, the prints dry and can be removed from the press.

Glazers of this type are made to take from one to four 8 × 10 ins. prints and consume from 300 to 1,000 watts depending on the size.

Rotary Glazer. Wholesale photo-finishers, photographic agencies and others turning out large quantities of prints use power-driven automatic rotary glazing machines.

In these machines the glazing sheet takes the form of a large cylinder mounted on a horizontal spindle and turned by a small electric motor. The wet prints are fed under a squeegee roller at the base of the rotating drum and held in contact with the polished surface by an endless band of fabric.

Electric elements heat the drum from the inside, and the rate of rotation is adjusted so that the prints emerge dry and glazed from

ROTARY GLAZER. The prints are applied to the glazing surface of a rotating heated drum, and pressed in contact by the continuous apron. One revolution glazes and dries the prints.

under the fabric band after making about half a revolution in contact with the drum.

Such machines are intended for continuous operation and have an output of 1,000 to 2,000 $2\frac{1}{2} \times 3\frac{1}{2}$ ins. (6 × 9 cm.) per hour or an equivalent area of prints of other sizes. F.P.

GLAZING. When prints are made on gaslight or bromide paper, a glossy surface adds to the contrast and gives a better rendering of fine detail. So a glossy surface should always be used for small contact prints and all photographs intended for reproduction. Glossy paper as supplied by the manufacturer dries with a shiny surface, which can be further improved by glazing. The wet print can be glazed by squeegeeing it on to a clean polished surface.

For small scale glazing, almost any highly polished surface will serve, but a sheet of polished plate glass, free from scratches, gives the highest gloss. Many workers use chromium plated steel sheets, and thick celluloid and glazed pulp boards are also used. These replace the once-popular ferrotype plates made of enamelled iron which were cheap but had the disadvantage that they were easily damaged.

Preparing the Surface. The glazing surface must be clean. The best way of cleaning it is to rub it vigorously with a pad of cotton wool or clean rag soaked in methylated spirit. The surface is then dusted with French chalk and polished with a clean dry cloth. Or the surface may be polished with the following mixture:

Beeswax	2 ounces	50 grams
Turpentine	40 ounces	1,000 c.cm.

A few drops are applied over the whole surface with a piece of clean rag, after which it is polished with a clean dry cloth.

Glazing Solution. When prints are simply squeegeed on to a polished surface they often have an annoying tendency to stick. This tendency can be overcome and a much higher gloss given to the surface by using a glazing solution.

For those who like to make up their own, the following formula is offered:

Prepared ox gall	½ ounce	12 c.cm.
Water about	40 ounces	1,000 c.cm.

The prints are soaked in the solution for about five minutes before glazing.

There are a number of proprietary glazing solutions on the market. These solutions may be applied direct to the glazing surface in their concentrated form, or they may be diluted to make a bath in which the prints are soaked.

After the prints have been allowed to soak in the dilute solution they are removed one at a time and the surface is lightly swabbed with cotton wool to remove scum or small particles of grit. The print is lowered to the glazing surface one end first so that no air is trapped between the print and the glazing surface. If the concentrated solution is used it is rubbed lightly over the polished surface and the prints

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

are laid on it straight from the final washing water.

To ensure even glazing, the prints are best squeegeed on to the plate once they are in position. A suitable method is to cover the prints on the plate with a rubber sheet and gently squeegee from one end to the other with a flat or (preferably) roller squeegee. After that the plate is drained, the rubber sheet replaced and squeegeed again more firmly. Finally it is advisable to blot off all surplus water from the back of the prints before letting them dry or inserting the plate into a hot glazer. When completely dry the prints should fall off.

In wholesale photo-finishing the prints are squeegeed on to a polished chromium-plated drum or sheet and dried off in a few minutes by artificial heat. These hard-worked surfaces are kept clean by washing them frequently with hot water and soap.

It is not necessary with modern papers to harden the prints before glazing as the emulsions are sufficiently hardened during manufacture. As a precaution, a fixing-hardening bath should be used in the tropics or in very hot weather. Prints that have not been hardened take the highest gloss.

Faults in Glazing. If good quality paper is used and the glazing surface is kept scrupulously clean most glazing troubles will be avoided. There are, however, some faults that have other causes:

Prints refuse to strip after drying: generally caused by a dirty surface, or exhausted glazing solution. If the trouble is very frequent, it can be avoided by drying the prints first, and then soaking them for ten minutes before glazing.

Small unglazed specks: squeegeeing is to blame and is failing to make perfect contact between the print and the glazing surface. Or small particles of grit in the washing water may be clinging to the print and keeping it out of contact with the glazing surface.

Oyster shell markings: these are caused by patchy drying through the uneven application of heat, or changes of temperature during the drying period.

Glazing Matt Surface Prints. A matt surface shows less detail than a glossy surface and it also has a shorter range of contrast. For this reason, matt surfaced prints are preferred for pictorial work where a slight suppression of hard detail is often an advantage.

But a matt surface print can be glazed when necessary; it may be that the negative is not available and the print is needed for photo-mechanical reproduction. Glazing is also helpful when a print upon a matt surface paper is to be copied.

It is never possible to produce a very high glaze on a matt surface print, but it can be made about equal to the surface of a glossy print before glazing.

A matt print can be given a gloss with a

GLAZING. The steps involved are: 1. Clean the glazing plate thoroughly, then pour a few drops of water on to it. 2. Carefully lower the print on to the glazing plate. 3. Tap the back of the print with the fingers to expel any air. 4. Squeegee down, first in one direction, then in the other 5. Place the glazing plate into the hot glazer, and fasten down the cloth apron, then leave until dry. For cold glazing blot off surplus water, and leave the plate to stand on edge until dry.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

varnish made up by diluting printer's white spirit varnish (as used for finishing show cards) with a little turpentine and spirit. The varnish is applied on a pad of cotton wool or clean rag with a circular motion over the print surface. It is essential to make the application as even as possible. The varnish takes several hours to dry, therefore the whole operation must take place in a dust-free atmosphere. A number of trade preparations can be bought for use instead of the varnish recommended above; these are sold under various names. R.M.F.

Books: *Enlarging*, by C. I. Jacobson (London); *The Complete Art of Printing and Enlarging*, by O. R. Croy (London).

GLOSSIES. (Slang.) The more expensively produced illustrated weekly and monthly magazines, so called because they are printed on highly finished art paper (ideal for reproducing photographs by the half-tone process).

GLOSSY PAPER. Photographic printing paper with a smooth shiny surface that can be further emphasized by glazing. It is almost essential for prints used for reproduction.

A glossy surface is devoid of surface texture and is thus invisible—like the surface of a polished mirror. It therefore shows up all the detail in the photograph. This is an advantage with small prints; it explains why they look so much clearer than prints on unglazed or matt papers; it is also the reason why glossy paper is used for technical photographs. Because the smooth surface does not scatter light, a glossy print can show much deeper blacks, and thus is able to cover a greater brightness range and reproduce shadow detail better than a rough surfaced print.

The light reflected from the fullest black on a glazed glossy print is of the order of 1–2 per cent of the incident light, while on a matt print it is around 5–10 per cent. Assuming a maximum reflectivity of 80–90 per cent from the pure white paper, the brightness range of a glossy print can be as high as 50 : 1, and of a matt print about 15 : 1 or 10 : 1.

The increased brightness range is also important in copying for photomechanical reproduction; and explains why prints on glossy paper always reproduce best.

But the glossy surface has disadvantages for ordinary prints. Because it shows up detail, it tends to emphasize graininess, scratches and other blemishes. Under-exposed shadow areas show up as featureless black patches on glossy paper, where a matt or textured surface would break them up and make them less noticeable.

Finally, it is difficult to retouch a print on glossy paper without the work being visible.

GLUE PROCESS. An obsolete variation of the gum pigment process for making prints. The paper is coated with pigmented glue, sensitized with potassium bichromate and the soluble glue washed off in warm water after the print has been exposed through the paper stock.

GLYCERINE. Used to thicken reducers, etc., for local application; also when enlarging scratched negatives.

Formula and molecular weight: $(CH_2OH)_2$ CHOH; 92.

Characteristics: Colourless oily liquid with sweet taste.

Solubility: Mixes with water in all proportions.

GLYCIN. Para-hydroxyphenyl glycine; Kodurol. Developing agent.

Formula and molecular weight: $C_6H_4(OH)$ $(NHCH_2CO_2H)$; 167.

Characteristics: White powder.

Solubility: Practically insoluble in water, but freely soluble in solutions containing sodium carbonate or other alkali.

GODDARD, JOHN FREDERICK, 1795–1866. Science lecturer in London; was employed by Beard and Wolcott to speed up the daguerreotype process by chemical means. Published his successful application of bromine as an accelerating sensitiser on 12 December 1840. This shortened the exposure from about 15 minutes to about 2 minutes, thus constituting a major improvement in the daguerreotype process.

GOERZ, CARL PAUL, 1854–1923. German optician. Founder (1886) of the C.P. Goerz A.G. works in Berlin-Friedenau. Manufactured cameras from 1888 and the famous Dagor double anastigmat lens (calculated by von Hoegh) from 1893; also the wide-angle Hypergon (1900), cine apparatus, optical instruments and telescopes. Introduced race finish photography in 1922. The factory later merged into the Zeiss-Ikon A. G. combine.

GOLDBERG WEDGE. Sensitometric wedge giving a continuously increasing density from one end to the other. It consists of a layer of gelatin which is thicker at one end than the other—i.e., wedge shaped. The gelatin is evenly tinted and, because of its varying thickness, gives a changing density. The gelatin is sandwiched between glass.

See also: *Sensitometry; Wedge.*

GOLD CHLORIDE. Chlorauric acid. Used in gold toners.

Formula and molecular weight: $AuCl_3$. $HCl.4H_2O$; 412.

Characteristics: Very hygroscopic yellow crystals.

Solubility: Highly soluble in water.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

GOLDEN SECTION. (Sectio aurea.) A term derived from interpretation of classic architecture and referring to the division of a line in such a way that the smaller division is to the longer as the longer to the whole. The resulting proportions have been claimed to yield ideal rectangular picture shapes. Loose usage of the term led to the belief that this point of division could also be used as a fulcrum of pictorial composition by only approximating the calculations involved.

See also: *Composition.*

GOLD POTASSIUM CHLORIDE. Used in gold toning baths.

Formula and molecular weight: $KAuCl_4.2H_2O$; 416.

Characteristics: yellow deliquescent crystals. Should be kept in the dark in sealed tubes, or as a 1 per cent solution in distilled water.

Solubility: Highly soluble in water.

GOLD SODIUM CHLORIDE. Gold sodiochloride. Used in gold toners instead of gold chloride, where a neutral solution instead of the acid one produced by gold chloride is required.

Formula and molecular weight: $AuCl_6.NaCl.2H_2O$; 428.

Characteristics: Hygroscopic yellow crystals.

Solubility: Very soluble in water.

GOODWIN, HANNIBAL, 1822–1900. American clergyman and amateur photographer. Filed in 1887 a patent application for celluloid roll-film. The patent was granted in 1898 and confirmed in 1914 after a long lawsuit against the Eastman Kodak Company.

GOST SPEED. Film speed rating in use in the Soviet Union and some eastern European countries. GOST speeds are quoted on an arithmetical scale and are fairly similar to the A.S.A. arithmetical speed numbers. The GOST speed criterion is based on the exposure point corresponding to a specified minimum density above base plus fog of the film.

See also: *Speed of Sensitized Materials.*

GRADATION. Term referring to the tone scale or contrast range of a developed image. An image which shows a large number of intermediate tones of grey between the extreme dark and light tones is said to have a soft gradation; if there are only a few recognizable shades of grey between the extreme dark and light tones, it is said to have a hard gradation.

The gradation of an emulsion is at once obvious from the steepness of its characteristic curve. An emulsion with a steep curve will possess a harder gradation than one with a shallow curve. If both emulsions receive the same range of regularly increasing exposures, the hard emulsion reaches maximum density in a few steep steps while the softer must be taken up a greater number of shallow steps to reach the same density.

Generally speaking, where the subject contains a large number of tones which must be reproduced to convey a true impression of its appearance—e.g., a rounded surface—a soft gradation sensitive material must be used. Where there are only a few intermediate tones—e.g., in a silhouette or in deliberate posterization—a hard gradation is more suitable.

There is a fairly constant relationship between speed and gradation: slow materials tend to have a hard gradation and fast materials a soft gradation.

Speed is generally the important factor in deciding the choice of a negative material, but development papers are classed according to their gradation, and speed in this case is unimportant.

Development and developers exercise a definite effect on the gradation of an emulsion. Broadly speaking, extended and concentrated development tends to give hard gradation and curtailed and dilute development gives soft gradation. F.P.

See also: *Contrast; Negative materials.*

GRADE. Classification of the inherent contrast in printing papers (which are usually obtainable in a range of different contrast grades).

See also: *Papers.*

GRADIENT. Slope of the characteristic curve of the emulsion at any point, and a measure of the contrast of the image at that point.

GRADUATE. Graduated vessel—usually of glass—for measuring the volume of liquids. Normally scaled with etched or painted figures.

See also: *Measure.*

GRAIN. The normal negative image consists of black metallic silver distributed more or less in proportion to the light that acted on the material during the exposure. Areas that received a relatively great exposure show a greater image density than those receiving less exposure. But the silver forming the image is not as evenly distributed as it appears to the naked eye. Examination under the microscope reveals that it is made up of irregularly shaped clumps of black silver. These clumps are formed by groups of the original exposed silver bromide grains after development has changed them into black metallic silver. While the grains appear to have grown together to form the larger masses of silver visible under the microscope they do not as a rule touch, and the apparent clumps are the result of the random distribution of the original halide crystals in the photographic emulsion.

In addition to being visible under the microscope, the grains also become apparent in the

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

print when the negative is enlarged. The grains then tend to break up the image and give it an unpleasant, mealy appearance. This is the reason why so much attention is given to the elimination or reduction of grain by manufacturers and photographers.

Speaking generally, the grain size of an undeveloped photographic emulsion increases with its sensitivity so that fast emulsions have a coarser grain than slow ones. The grain in a developed emulsion also tends to increase with the size of the crystals in the undeveloped emulsion and as a rule it increases with the development time.

Graininess and Granularity. The graininess of a developed photographic material refers to the appearance of the finished photograph and may be defined by the distance from which a photograph has to be viewed to make the grainy impression disappear completely. On the other hand granularity is physical and may be defined in terms of the local changes in density when a narrow pencil of light scans the test patch. Both granularity and graininess are subjects of a great deal of present-day research, one of the aims being to define a method of determining the granularity which will link it with the grainy appearance of the picture. The problem has largely been solved in recent years.

There have been many attempts to define granularity, of which that proposed by Selwyn in 1935 has found general acceptance. If the density of a piece of uniformly exposed and processed photographic film or paper is measured in a densitometer, in which the diameter d of the measuring aperture can be varied, density values taken at different points will differ, more so the smaller the size of d. This is because the population and size of the developed grains is not completely uniform. The density values measured with any one aperture will cluster around the average value, which would be obtained with a very large aperture, and will in general follow a bell-shape Gaussian distribution, the shape of which is determined if the spread σ is known. 2σ is the range between which 68 per cent of all measured values will lie; 999 out of 1,000 measurements will lie between 6σ.

Selwyn's relationship between the value of σ for a given average density and the diameter d of the measuring aperture is simply:

$$\sigma \times d = \text{constant}$$

The constant is termed granularity.

In practice, granularity is determined on a scanning microdensitometer, the fluctuating output of which is fed into a so-called rms (root mean square) voltmeter, on which the values of σ may be read directly.

The granularity increases with density, since with higher density the number of grains per unit area, and thus their fluctuation, is greater. In order to describe completely the granularity of an material, an array of curves, plotting granularity against density, would be necessary. The arrays vary for different emulsions and conditions of processing, but they are sufficiently similar to allow the granularity of a material to be represented by a single figure with reasonable accuracy.

For this purpose the granularity value for a certain density is conveniently chosen. Two conventions have been proposed and termed Class I and Class II granularity.

Class I granularity is used for the routine evaluation of negative materials of one type and is simply the granularity at a density of 0·8 (including fog, but excluding base).

For a granularity figure which is more representative of what might be seen in a print, Class II data are necessary. Here the negative is developed so that the average slope of the characteristic curve falls between the limits laid down for the determination of speed; this would be $0{\cdot}65 \pm 0{\cdot}05$ for amateur black-and-white films, and around 0·8 for commercial films. Granularity is then determined at a density of 1·2. In this way a good correlation between granularity and the graininess of the print is established.

The Print. Graininess in the print is always worst in the middle tones. The grains of paper emulsions are always much finer than those of negative emulsions and the positive image is—where graininess is a consideration—usually an enlargement of the negative; consequently, the graininess of the print is essentially due to the negative image. The print graininess is low in the highlights where a small change in density in the negative is reproduced by a much smaller change in density in the print because here the emulsion is being used in the region of the toe of the characteristic curve for the paper.

Graininess is also reduced in the deep shadows, since here the eye is not as sensitive to small changes in density.

Granularity in the print is affected by the granularities of both negative and positive materials. When the scanning aperture is small, the granularity in the print will be essentially that of the positive material. For larger scanning apertures, the granularity will be more nearly governed by that of the negative, and will represent more nearly what is perceived by the eye as graininess. The granularity in the print measured with larger apertures also depends on the contrast of the positive material, since densities will be simply proportional to the density of the negative multiplied with the slope of the positive curve. Since for an average good photograph the Goldberg condition applies:

$$\gamma \text{ neg} \times \gamma \text{ pos} = 1{\cdot}5$$

one may define as print granularity the negative granularity divided by γ neg.

The Negative. The graininess of the negative increases continuously with density provided

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

the light flux behind the negative, i.e. on the viewing side, is kept constant. A heavily exposed and consequently dense negative therefore yields a much more grainy print than one normally exposed.

This makes it important to choose the camera exposure correctly.

Similarly a print from a foggy material tends to be a good deal more grainy than one from a clean negative.

The fact that the photographic image is built up from a large number of small grains limits the degree of enlargement which can be used in practice, for two reasons. One is that the grainy appearance is often considered unpleasant, the other that the presence of grain limits the resolving power of a photographic material so that the picture appears blurred if enlarged unduly.

The concepts behind these well-known facts have been refined in recent years. Granularity has the same properties as the "noise" in a wireless receiver; i.e. it obscures the intelligibility of the signal. In order for a signal to be clear—and this can only be stated within given probability limits—it must exceed the noise the more the greater the certainty required that the signal is genuine.

For a small area of density to be clearly distinguishable from its surrounding areas, it must exceed these so much that only a few density steps may be clearly distinguishable within the tone range provided by a photographic material. For larger areas, more steps will be available. The detailed discussion of this situation is the task of information theory. W.F.B.

GRAIN (WEIGHT). Smallest unit of weight used in all British and American systems of measurement.

See also: *Weights and measures.*

GRAININESS. Mealy appearance of the printed image caused by the clumping together of the silver grains forming the negative.

See also: *Grain.*

GRAM. (French: Gramme). Unit of weight in the metric system related to the other units by powers of ten.

See also: *Weights and Measures.*

GRANULARITY. Term referring to the structure of the sensitive emulsion as represented by the measured variation in the distribution of an apparently uniform silver deposit. It is a scientific concept whereas graininess is a subjective impression; a highly granular, but very dense deposit would appear less grainy than a lighter deposit which was observed by the eye at a correspondingly more discriminating level of visual acuity.

See also: *Grain.*

GRAPHIC ARTS. A comparatively modern term covering all the processes of making reproductions of illustrations for printing purposes. The hand- or machine-setting of the type characters to form the text is not usually included in the term, nor is the machine-printing of the end product. An exception is the processing of the product (i.e. the exposed photographic film) of photo-composing (filmsetter) machines.

Camera Work. Graphic arts cameras vary in size and complexity from small simple ones providing a maximum negative size of 12 × 15 ins. to large, high-precision motor-driven equipment which may weigh several tons and give negatives of 40 × 60 ins. or more.

Originals (generally called copy) for reproduction may be photographs, drawings or paintings, while colour copy is often in the form of colour transparencies. The copy is placed on the copyboard of the camera and lit evenly with arc lamps or, in the case of transparencies, illuminated from behind, then photographed to obtain one or more negatives. High-precision enlargers may also be used for this work, especially when involving colour transparencies. The initial continuous-tone separation work is done on special contact-printing boxes, which use a vacuum to hold the original in close contact with the photographic film. In common with the cameras and enlargers, they also have mechanical or electronic timers for controlling exposure, mechanical drive to change the colour filters, and pin register for locating copy, film, colour, masks, etc.

Black-on-white pen-and-ink line drawings are usually photographed on very high contrast (mainly silver chloride) photographic emulsions of the lith type, where the lines are recorded in the negative as completely clear transparent areas in a dense, opaque ground. For letterpress plate-making, the negative is contact-printed on zinc (sometimes on copper) in a light-sensitive colloid substance which can then be baked to form an acid-resisting enamel. The metal surrounding the lines is then etched, leaving the raised letterpress image.

For lithography, the line negative can be contact-printed on the litho metal (commonly anodized aluminium) to form a grease-based ink image. When the plate is stretched tightly around the plate cylinder of the press and damped with water, the image area accepts the ink, which is repelled by the damp areas. This image is then transferred to the offset blanket (a tightly-stretched layer of mid-hard rubber on the offset cylinder) and from there to the paper by pressure; hence the term "offset-lithography".

For photogravure, a line positive is used to

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

form a light-hardened gelatin negative image on the copper cylinder. The gelatin resist, thickest in the white areas and thinnest in the black, is etched in ferric chloride solution, which penetrates the thin gelatin layer in the areas of the lines of the image, but is too viscous to penetrate the thicker areas. Thus the lines are etched into the copper. The screen pattern of thin lines at surface level, which support the scraping action of the doctor blade when printing, is separately exposed when making the carbon print.

Tone Illustrations. For pictures containing a tone range, the half-tone dot formation negatives for letterpress work are made on graphic arts cameras with a half-tone screen supported in front of the film. After processing the latter is printed on metal in an acid-resisting enamel, much as for line work, and possibly etched by the powderless technique. But it is usually necessary to include, at some stage of the work, an adjustment of the tones of the picture, to correct the inherent shortcomings of the photographic stage and to allow for the requirements of the printing method.

For lithography, the plates may be contact-printed on the metal from line and half-tone negatives. More often the plates are made from line and half-tone positives, which, in the case of the half-tone images, may well have been prepared by photographing continuous-tone negatives through a half-tone contact screen. In that case, the retouching for tone correction is usually carried out partly at the negative stage (chiefly for the light tones) and completed on the half-tone positives.

For photogravure, positives are required for making the etch resist on the cylinders, and for conventional photogravure the positives are in continuous tone. The retouching is therefore in continuous tone for both negative and positive and it is convenient to treat the dense tones of each; that is, the light tones of the negative and the dark tones of the positive, which are appropriately strengthened with neutral grey dye.

Dot Etching Retouching. The retouching of half-tone negatives or positives is rather different from continuous tone retouching, because the size of the dots needs to be altered. Dye retouching is unsuitable because it would affect the amount of exposure of the dot formations and thus the printability of the plate. Dot images have to be "all-or-nothing"—to print or not to print. Hence the dot size must be reduced—usually with ferricyanide-hypo which may be applied locally with a brush. Alternatively, parts of the picture may be covered with a cellulose varnish and the whole bathed in the reducer solution. Knife scraping and abrasive reduction are other, less-used, methods.

Colour separation images require not only tone correction but colour correction. This work requires great skill but it tends to spoil colour photographs, making them resemble paintings. To avoid this, photographic colour-masking techniques effect at least some of the necessary correction, making less retouching necessary. Electronic colour correction is an even more automatic system of masking; it is particularly effective for providing the necessary quality in the black printer plate and in reducing the weight of the colours in the neutral colours, which are best made with the black printer.

GRATICULE. Pattern of fine lines superimposed on the visible image in a piece of optical equipment to facilitate sighting, aligning or measuring. Known in America as reticule or reticle. There are many kinds for varied applications, including such optical aids as microscope stage micrometers, divided circles employed in theodolites and other surveying instruments, master templates for profile projection, scales for linear measurement, and cross-lines grids as used in the focal plane of instruments such as telescopes, microscopes and binoculars.

A graticule is usually considered to be made up of two parts. One is the support or blank, usually of glass but sometimes of metal or plastic material, and the other is the pattern. According to the nature of the pattern and its relationship to the associated optical or mechanical device, the graticule may be used for a variety of purposes including measurement of length, angle, area, volume, or for reference when positioning an instrument.

The uses of graticules in everyday photography are not extensive but one important application is in aerial survey cameras which employ a so-called register plate on which is a graticule pattern reproduced on each photograph as an aid to subsequent measurement. Again, in assessing projection-lenses a resolution-test graticule is often used thereby enabling the viewer to make some estimate of the lens performance.

Modern graticule-making processes are very numerous; they range from those employing photography almost exclusively to those which mainly involve mechanical techniques. Etching applied to glass itself or to metal films on glass is frequently employed. Modern developments have taken advantage of the many benefits to be derived from the use of vacuum-evaporated or sputtered metal films.

Since in most applications clarity of vision is of prime importance photographic processes for producing the final pattern have not, in general, been of the conventional gelatine-emulsion type. The use of alternatives—bichromated fish-glue, polyvinyl alcohol, shellac, and more recently synthetic photo-sensitive materials—has been widespread because, among other attributes, they possess the valuable property that after exposure and

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

development the unexposed areas are completely removed. Nevertheless, sometimes high-resolution gelatine emulsions of the Lippmann type are employed for the final pattern but in such cases exceptional care must be taken to ensure cleanliness.

In many processes which are mainly based on photography the original almost invisible colloid image is intensified by introducing darkening agents such as lead sulphide, colloidal silver, or certain dyes. For more permanent patterns it is often necessary to etch the lines and figures in the glass surface after first preparing on it a protective metal or other stencil. Other processes involve heat treatment of a metal or the introduction of metal into the glass itself under the influence of an electric field. More recently, permanent graticule patterns have been prepared by using photo-sensitive glass which yields the appropriate image after exposure to ultra-violet radiation followed by heating. E.Bo.

GREETING CARDS. The photographer has the opportunity of producing original greeting cards which will appeal more to the recipients than the mass-produced cards sold in the shops. He can make Christmas cards, birthday cards, baby arrival cards, bookmarks, gift cards, wedding congratulation cards, wedding anniversary cards, or "get well" cards. They can be produced in many ways and range from straightforward prints to those made by photomontage, or from black-and-white to colour.

Simple Cards. The simplest greeting card can be made by pen lettering a greeting with opaque ink on the back of a film negative, and then printing by contact or enlarging. This can be done by anyone, and is easier than trying to write a greeting in reverse on the film side of the negative, or making a copy negative of the combined greeting and illustration.

Another simple method is to put the photographs in commercial printed folders. This, however, can hardly be claimed as making greeting cards.

A development of this idea—and one which is attractive—is to use master masks for the greeting part of the card. These can be obtained commercially and with a wide range of designs, but it is not difficult to make them at home. An original is first drawn in Indian ink on white paper to conform with the size of the finished cards. A space is left where the illustration is to be printed later. The surround can be decorated with a fine line or fancy bordering, or the whole area can be left completely blank, so that the picture has a white border when printed later.

A copy is now made on a process or line film and developed in a maximum contrast developer to obtain a good contrasty negative. This copy can be made on one of the special thin base process films, and then later an opening can be cut out to allow the film negative to be inserted below. The combination when printed by contact will be perfectly sharp. The size of the copy negative will depend on the size that the finished card is to be. If the illustration is 2 × 3 ins., then half plate size would be suitable for the master mask negative. This idea is also useful in that a few copies can be printed from each of a selection of different negatives, instead of having to keep to the same illustration on every card.

After the film is dry, the opening for the subject negative is cut out, and the negative taped in place. A piece of cellulose tape is ideal for this purpose and, as the background negative has great density, it will not show. The opening for the illustration negative can be cut with a sharp penknife or a razor blade, and a steel rule and set square. It is important that the edges are clean, square and straight.

If glass plates are used for the background negative instead of film, the window for the illustration negative can be cleared by scraping off all the gelatin emulsion from the glass base. When the film is placed on this and printed by contact, there will be some very slight softening of the background design unless a great deal of pressure is used to secure optical contact. The cards can be printed from such a multiple negative, however, by projection in the enlarger. It may be necessary to shade either the illustration or background negative during exposure to give the same printing density to each part.

Folded Cards. A variation on the above method of making photographic greeting cards is to use a much larger sheet of photographic paper for the greeting card background and then double or four-fold it, to improve on the ordinary flat greeting card. This looks effective, but, if expense is a consideration, the large size photographic paper needed for this method is costly. For example, to produce a four-fold card size 4 × 5 ins. needs a piece of 8 × 10 ins. photographic paper for each card.

If a two-fold or a four-fold card is made it can have a touch of colour added with a bow or knot of ribbon tied at the side. Selecting the colour of the ribbon to blend with the picture can add extra appeal—e.g., by combining a tartan ribbon with a highland scene, or using regimental colours on a soldier's camp photograph.

The manufacture of the two-fold or the four-fold card does not require much special description, but there are one or two points to watch. First, the illustration and greeting must be so placed on the paper that they come into correct alignment when trimmed and folded. Again, the prints should not be dried by heat, otherwise the gelatin emulsion may crack when folded. While single or double weight photographic paper can be used, the larger sizes of single weight paper may crease when wet unless handled very carefully.

Where greeting cards are to be made by the more complicated methods—e.g., photomon-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

tage or photograms—it is better to make a key original and make a copy negative from this, for the making of a number of photomontage or photogram cards by direct methods can be costly and tedious.

Anyone not an expert at lettering, can use stencils, nursery, cut-out letters, cine titling letters, or draw the letters with a pantagraph, to word the greeting. Another way is to use the actual handwritten signatures of the people in the photograph, or to put the greeting in script lettering. Illustrations for the background can be traced, stencilled, or caricatured, methods which call for very little drawing skill.

Mounting and Colouring. Where photographs are to be mounted on to board to make a greeting card, they should be dry mounted and not wet mounted, to avoid cockle. Cover boards can be purchased from artists' sundriesmen. They should tone with the colour of the photograph to show the picture off to best advantage. Boards which are ornate in finish, or glaring in colour, should not be used. Pastel shades are generally preferable. A white board is best for black-and-white prints and ivory or cream toned board for the sepia and warm tones. Tinted base photographic papers can also be used with advantage for some subjects—e.g., photographs of sunsets, cornfields, autumn scenes, or golden sands.

Colour can be introduced either by using actual paper colour prints, or by making use of the less costly hand-colouring methods. Where a number of hand-coloured prints are to be made of one subject it pays to cut stencils out of waxed paper for the principal objects, or the "rubbing-on" oil colouring method can be used. Here, all one part of all the cards is coloured at one time—e.g., skies or sea. This method also saves colouring time. Colour can be introduced into the background of the cards by drawing something in the illustration suitable for tinting—e.g., holly and berries, a lantern, the traditional robin, bluebirds, thumbnail sketches of flowers, windmills, etc.

If a large number of greeting cards are required in colour, genuine colour photographs made by the dye transfer colour process are quicker to produce and relatively cheap.

Suitable Subjects. As subject matter for the illustrations, either general pictures can be chosen or those with a personal interest. For Christmas cards, such subjects as snow scenes and old buildings and churches are suitable. For birthday cards beautiful scenes or subjects which have some personal associations for the recipient are quite apt. For baby arrival cards and wedding anniversary cards, have a family motif. A good camera study of the church where the pair were wed would provide something which no commercial card could give. Gift greeting cards should be of pleasant, decorative subjects. Greeting bookmarks offer unlimited scope for both ideas and subjects, and "get well" cards can be treated seriously or in lighter vein. Humorous table top photographs or happy snapshots can do much to cheer up a depressed patient.

All types of photographic greeting can be improved by a little originality in presentation.

Deckled edged mounts can be made by clamping the mounting card (in bulk) between two pieces of plywood or hardboard, the same size as the cardboard, in a vice and drawing the point of a large nail cross-cross over the edges of the card.

Hand torn edges can be made by placing the card on a flat surface, putting a steel straight-edge on the top of it, and pulling the surplus of the paper edge upwards, while holding the steel rule very firmly on top of the photographic paper or mounting card. At least 1 in. extra must be allowed all round the board to grip while tearing. A.Pg.

GRENZ RAYS. Soft X-rays used for the industrial radiography of textiles and materials with too small a range of densities to give an image with normal X-rays.

GREY SCALE. Print or transparency consisting of a series of grey tones extending in regular steps of increasing depth of tone from white (or clear) to black (or opaque). Grey scales are used as test objects in sensitometry and for adjusting exposure and development to give true colour balance in making three colour separation negatives.

See also: *Wedge.*

GROTTHUSS, THEODOR FREIHERR VON, 1785–1822. German pioneer in photochemistry. Discovered (1817) the basic law, that, "only the absorbed light rays are active in the production of chemical changes. This law, the Grotthuss law of photochemical absorption, was named after him. It was later forgotten and re-discovered by Draper (1841). Among his numerous photochemical experiments are some on the bleaching of dyes by light of different colours.

GROUND GLASS. Plate or sheet glass which has been abraded on one face to give a translucent, light-arresting surface on which a visible image can be formed. It is the standard material for making focusing screens for field and reflex cameras.

See also: *Focusing; Focusing screen.*

GROUPS. The fashion in group portraiture has changed more than in any other branch of photography. The florid "draping" of the sitters in groups of forty or fifty years ago has now given place to neat, formal posing.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

POSED FORMAL GROUP. The regular arrangement ensures that everybody is well visible in the picture. Such photographs of sport teams should include reserve players and club officials as well as trophies in the foreground.

Large Groups. Groups involving 100 sitters or more are usually taken with a panoramic camera. This gives a negative 6 ins. or more in depth and as long as the group demands. Prints up to 3 feet in length are not uncommon. This type of work is largely in the hands of specialist firms who act for other photographers on a trade basis.

Medium Groups. Groups up to 100 sitters are commonly taken on a ½-plate camera and the negative subsequently enlarged to the required size. Such plates (or cut-films) are normally processed in fine-grain developer to ensure maximum, grain-free resolution of each sitter's face. In order to make maximum use of the plate area and to produce a print of pleasing proportions, it is customary to "bank-up" the group as much as possible. In a typical arrangement for a school group of 100 persons, 20 of the smallest pupils would be sitting cross-legged on the ground; 20 (staff and senior pupils) sitting in chairs; 20 standing immediately behind them; 20 standing on forms; and a final 20 standing on tables forming the rear rank.

The photographer is careful when marshalling the group to arrange for even balance of height in all ranks—normally he puts the tallest pupils in the centre and allows the ranks to tail away to the sides of the group. A group always looks better if all the members adopt the same pose: either all arms should be folded or all hands should rest in laps; all ankles should be close together or all knees crossed. The exact arrangement rests with the photographer, but uniformity is essential.

Smaller Groups. Into this category come such assemblies as cricket XI's, football teams and other such sporting groups. The usual arrangement for an "eleven" makes use of five chairs only. The captain sits in the centre chair with two players on each side of him. The six remaining members of the team stand behind the seated five covering the gaps between the sitters. Trophies, if any, are placed on the ground in front of the captain.

Occasionally teams wish to be photographed holding their sports gear—e.g., tennis racquets, hockey sticks or rifles in the case of a shooting eight. Particular care is then taken to get the members to hold their gear in a uniform manner or the final effect will be ragged and untidy.

Family Groups. Here are included groups taken on the diverse occasions on which families foregather to celebrate some notable event. Strict formality is not appropriate to such groups; the photographer aims at achieving a sense of relaxed, comfortable unity. It is customary for the central characters to be seated with the women seated beside them. The men stand and the children are seated on rugs on the floor.

Informal Groups. Such seemingly simple pictures call for the highest degree of technical and creative ability. The formal group is a comparatively simple matter—sitters are posed in conventional fashion and all eyes look towards the camera. In the informal group, the reverse should be the case. There should be some central point of interest to create a sense of artificial unity. A high viewpoint is desirable in many cases so that the camera may appear to be, as it were, an eavesdropper to some notable occasion.

To cite examples: a trophy has been presented to a golfer and the picture shows, from a 7-foot viewpoint, a re-staging of the presentation. All involved are closely gathered around and vigorously clapping hands are seen. Such a treatment is more effective than a formal line-up. A similar theme from a different viewpoint would be treated as follows: the wedding cake is about to be cut and all concerned are grouped closely around the table. The photographer exposes from a very low viewpoint to stress the style and elegance of the gowns worn by the ladies.

Whatever the subject chosen for an informal group, care should be taken that none of the sitters appears to be aware of the camera's existence. This means adopting a technique similar to that for candid photography, in which various methods are used for concealing the camera—e.g., aiming the camera "blind" from inside an open coat.

With many informal groups it is important to capture the atmosphere of the occasion too.

STUDIO FAMILY GROUP. A suitable settee holds the group together. The adults sit "backwards" to keep their legs on the far side of the settee. Toys add atmosphere. Relaxed poses and expressions are important.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

POSED INFORMAL GROUP. The arrangement of the figures is less regular, but still carefully set out. Bodies are posed so that they tend to face inwards to the centre of the picture.

This may mean including in the picture certain objects that are a feature of the surroundings, choosing the position of backgrounds carefully, and selecting the right moment for making the exposure. The choice of viewpoint, influencing the composition, can also play an important part in getting the atmosphere—for instance, a group of chorus girls may look more agile and full of movement if the picture has strong diagonal composition rather than static, horizontal emphasis.

It is, of course, possible to "stage" an informal group beforehand. This involves careful handling and direction of the people if the effect is to look natural. Usually it is better to work out a rough arrangement and make the exposure when the people have relaxed and forgotten the photographer's intentions.

Commercial studios often arrange informal groups for advertising pictures. These are frequently taken in the studio—even if the setting is an outdoor one. In this case, professional models are mostly used, experienced in posing naturally. Photographs of this type are more complex in setting-up than the final picture suggests, and involve much patience and attention to minor details. But the same advice as for other informal groups still applies.

Lighting. Large groups indoors are best lit evenly from both sides, so that shadows more or less cancel each other out. Such lighting can consist of floods or flash.

When working outdoors it is wise to avoid direct sunlight, as this will cause unpleasant strained expressions and also cast harsh shadows. Soft daylight from a clouded sky is ideal. Diffused sunlight helps to give the picture some sparkle.

Backgrounds. In all groups the position in relation to the background is important. The chosen site must be level in a "left-to-right" plane and selected so that it avoids unsightly distraction in the background. A smooth, distant line of trees is almost ideal. Buildings in the background are avoided unless there is some very good reason for including them. The backs of buildings, with their unsightly drainpipes and other services, are particularly undesirable.

Audience Control. A photographer's success in handling large or small assemblies depends almost as much upon his personality and capacity to handle people as upon his technical ability.

The men who succeed in this exacting branch of photography are invariably calm and deliberate in their methods of working. They have no use for excitable patter, fuss, artistic antics or ponderous humour. G.Cg.

See also: *Banquets; Weddings.*
Book: *Group Photography*, by G. Catling (London).

GUIDE NUMBER. Alternative name for the flash factor used in arriving at the correct exposure to give with a particular make of flash bulb. The number (quoted by the makers for a particular flash bulb, shutter speed, and sensitized material) divided by the subject distance, gives the recommended aperture.

Example: the correct *f*-number to use when taking a subject 10 feet away with a flash bulb of guide number 120 is

$$\frac{120}{10} = 12.$$

This assumes that a normal reflector is used.

Specific methods of measuring guide numbers as laid down in certain industrial standards. These involve comparing the densities obtained on a film exposed to a standard light source and to the flash under test. With flash bulbs the light is measured of the bare bulb and the resulting guide number multiplied by 2, assuming a reflector factor of 4. With electronic flash the measurement automatically takes into account the power of the flash reflector. The amount of light likely to be reflected from the walls of a room under normal conditions is also allowed for in the standard measurement method.

See also: *Flash technique.*

GUM ARABIC. Gummy substance obtained from the stem of the acacia and also occurring in the fruits of certain other plants. It is soluble in water, but becomes insoluble when treated with certain bichromates and exposed to light. Used in mountants, for sizing paper before sensitizing for certain processes, and in the gum bichromate process.

GUM BICHROMATE PROCESS. Contact printing process in which the image is formed on a coating of sensitized gum containing a suitably coloured pigment. Exposure to light renders the gum insoluble, so when the exposed paper is "developed" in running water the pigmented shadows remain while the highlights are washed clean.

The gum bichromate process can be made to yield prints of great beauty but it has been practically superseded in recent years by

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

bromoil and bromoil transfer. At the same time the gum print has a distinctive character of its own. There have been attempts at revival, although the technique is not easy to master.

Materials. The process calls for only a few inexpensive materials. These are: potassium bichromate 10 per cent solution; white gum arabic; moist water colours in tubes, or dry powder colours; paper for sensitizing (Whatman Cartridge, or good sized paper); one or two brushes, including mop, camel hair brush, and a 2½ ins. flat brush for smoothing (good quality paint brushes will serve).

Sensitizer. One ounce of gum arabic is dissolved in 3 ounces of water, preferably by placing the gum in a muslin bag suspended in water. The potassium bichromate is a 10 per cent solution made up with hot water. This is simply a saturated solution and it is near enough if there are always some undissolved crystals at the bottom.

The sensitizing solution varies according to the technique of the worker, but a mixture of equal parts of the gum and bichromate solutions will be found satisfactory. One part of ivory black or a rather smaller quantity of tube colour are added to every four parts of this solution. The two must be mixed with a glass rod until all trace of grittiness disappears.

Coating. The paper is pinned to a large drawing board over two or three thicknesses of blotting paper. The sensitizing solution is then applied with the coating brush in a series of brisk overlapping strokes from side to side. Then the smoothing brush is used to smooth out the coating with similar strokes from top to bottom. If necessary, any ridges still showing are broken up by going over the surface again with lighter strokes from left to right. When the coating is correctly carried out the coating will be smooth. The brushing is very lightly kept up until the pigment mixture has begun to set. The paper is then left in a warm dark place until it is dry.

When the coating works too stiffly and it is not possible to smooth out the brush lines, it is an indication that there is too much gum. If on the other hand the coating takes too long to set and small transparent patches appear, there is too little gum in proportion to the amount of pigment.

The paper is not sensitive until it is almost dry, therefore the coating can be done in bright artificial light.

The negative that prints best is one that is rather thin without strong contrasts, of the type that is regarded as ideal for enlarging.

Exposure. The print is made by contact with the negative in an ordinary printing frame by daylight or colour arc. There is only a slight visible image during printing and it is no guide to printing depth. As a guide, a piece of P.O.P. or self toning paper is put out at the same time under a negative of similar density and contrast. When the P.O.P. print is of the right depth for

GUM BICHROMATE PROCESS. 1. Apply the mixture of gum bichromate solution and pigment to the paper by a suitable brush. Work in subdued light. 2. Hang the paper up to dry in the dark. 3. Place the paper in a printing frame with the negative. 4. Print out by daylight, using a P.O.P. paper at the same time as a check on the progress of the exposure. 5. Develop by floating face down in a dish of cold water, or attach to a glass plate and wash off soluble gum by an artist's spray.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

toning and fixing the gum print is fully exposed.

Development. The print may be allowed to develop by leaving it face downwards in a deep dish of cold water. This allows the soluble gum and pigment to dissolve out in their own time. This may be anything from 15 minutes to 5 or 6 hours or longer according to the depth of the printing.

It may also be developed by a light spray. This method of development calls for a more fully exposed print. The print is first placed, coated side down, in water for 3 or 4 minutes and then taken out and laid upon a sheet of glass of larger size. Water from a spray of the type used for fixing artists' drawings is then directed on to the surface of the print. The highlight tones of the print can be controlled by varying the force of the spray; the stronger the spray the more pigment is removed.

When development is complete, the print is pinned up to dry. Great care must be taken not to touch the surface of the print while it is wet, as it is delicate and easily damaged at this stage.

Double Coating. The gum bichromate process allows of control over the contrasts of the print by the method of development adopted. This control can be extended by double coating. After the first print is made and finished, the surface is given a second coating, dried, registered under the negative and exposed a second time. The second development allows the same measure of control and can be made to yield a stronger, richer print. R.M.F.

See also: *Control processes, Impressionistic photography.*
Book: *Pigment Printing*, by G. L. Hawkins (London).

GUM PLATINUM PROCESS. The gum platinum process combines the gum bichromate and platinotype processes. A fairly light print is made upon platinum paper. This is then gum-sensitized and the print is registered under the negative a second time. The gum coating is then exposed and developed in the usual way.

GUN CAMERA. Aerial gunnery camera for recording strikes on the target in combat, and for use without ammunition in gunnery training practices, when it shows the accuracy of aim.

In its commonest form, it comprises an electrically-driven 16 mm. cine camera with, in the past a long-focus, but nowadays ultra wide-angle lens, aligned with the free guns in a turret or fixed forward guns in a fighter or bomber. In the latter case, the gun camera is also used to record rocket and dive bombing attacks, although these may also be covered by fast recycling still cameras on larger film.

The camera is actuated by the firing or release button, and usually continues running for some seconds after ceasing fire, to give the projectiles time to reach the target. During these seconds, the firing aircraft often starts violent evasive action so that, unless it has an ultra-wide-angle lens, the camera loses the target. Various counters to this have been tried, from devices to deflect the optical axis, to backward-pointing cameras for use during the pull-out from ground-strafing attacks. There remains the difficulty of seeing damage through flying debris.

Another gun camera, used in training, photographs through the actual gunsight, recording the sighting graticule as well as the target. Its pictures are particularly easy to assess.

In most cases the films are assessed by single-frame projection on a gridded screen. Where the target is another aircraft, the shadow from an identical model of the type is matched to the target silhouette. This shows the target's attitude and direction, and also the range. The increasing use of colour film has made assessment much easier.

Gun cameras are not confined only to aircraft. They are often used in close-range anti-aircraft gunnery, and similar instruments may be fitted to missile-tracking radar aerials. P.B.M.

GURNEY-MOTT THEORY. A theory of the way in which a latent image is formed in a sensitized silver emulsion by the action of light, proposed by R. W. Gurney and N. F. Mott in 1938.

It is generally accepted that exposure to light causes photolytic decomposition of the silver halide grains in an emulsion and deposits minute specks of metallic silver which form nuclei for the developer to start work on. As a result of the presence of one such speck on the surface of a grain of the halide, the developer is able to convert the whole grain into metallic silver.

The Gurney-Mott theory explains the mechanism of this photolytic action. It suggests that a quantum of light releases an electron from a halide ion, and that this electron attaches itself to an existing silver speck or nucleus. The electron carries a negative charge and this enables it to attract an unattached silver ion from the interior of the crystal and thus add a silver atom to the speck. In this way the speck builds up to form a starting point for the subsequent action of the developer.

H

HALATION. A photograph of a bright source of light is often surrounded by a sharply defined ring with a diffused outer edge. This effect is called halation and is produced by the fan of scattered light reflected from the back of the support of the photographic material.

Halation is minimized by reducing the support thickness, which decreases the diameter of the ring of reflected rays. This ring is smaller with films than with plates because the film base is thinner. It is also reduced by using a dyed backing layer to absorb the rays which penetrate to the rear of the support.

HALATION. Light scattered in the emulsion is reflected from the bottom of the support and at a certain angle forms a halo round bright image points (e.g., light sources in the picture).

Certain films are coated on a grey base which absorbs a lot of the light that normally reaches the emulsion by reflection from the back of the support.

Halation commonly occurs in night photographs where street lamps are included in the picture. Daylight interiors which show unshielded windows also suffer from halation; this occurs in the dark areas around the window.

Over-exposure also promotes the appearance of halation since the comparatively weak halo image then becomes developable. That is also why it is so apparent around brilliant over-exposed image spots.

HALF-FRAME CAMERA. Miniature camera taking 18 × 24 mm. pictures, yielding up to 72 exposures from a standard 35 mm. cassette. The term "half-frame" refers to the fact that the picture area is half of the full 24 × 36 mm. frame size. Cameras of this kind are popular as compact pocket models.

See also: *Miniature camera.*

HALF-PLATE. Standard format for negatives and prints, measuring $4\frac{3}{4} \times 6\frac{1}{2}$ ins.

A half-plate is not half of a whole plate; that size, $4\frac{1}{4} \times 6\frac{1}{2}$ ins., is not used in photography.

See also: *Sizes and packings.*

HALF-TONE BLOCK. Photomechanical printing block in which the printing areas are formed by a pattern of raised dots. The dots are small or large according to the tone of the original. Highlights are normally represented by very small dots which may, however, be removed by deep-etching or engraving if necessary. The shadow dots join to produce almost solid areas. An optical illusion of intermediate grey tones is produced by the varying proportions of dot and white paper corresponding to the half-tones of the original subject. Half-tone reproduction is used for reproducing photographs and other continuous tone originals.

See also: *Photomechanical reproduction; Scaling for reproduction.*

HALF-TONES. Grey tones intermediate between shadows and highlights in a picture. Sometimes also called middle tones.

HALF-TONE SCREEN. Line or dot pattern used to convert the continuous tones of varying darkness in a photograph, etc., into a discontinuous pattern of constant density but varying area. In a half-tone image lighter or darker tones are produced by smaller or larger dots on lines—which, through being uniformly spaced thus occupy a greater or lesser

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

proportion of a given unit area. This conversion into a half-tone image is necessary in lithographic or letterpress printing from continuous tone originals, because litho plate or letterpress block can imprint only a uniform ink density on paper.

Half-tone images can be produced in many ways; the most usual is to convert the continuous tone into a regular dot pattern. For this purpose, a glass cross-line screen can be used in a process camera to make screen negatives or positives, and a film contact screen can be used in a camera, in a contact box, or on an enlarger baseboard.

Cross-Line Screens. These are made from glass and carry equally-spaced parallel lines which have been etched and filled with an opaque substance. Two glasses are cemented together so that the lines cross at 90°. Screen rulings range from 50 up to about 200 lines per inch.

In letterpress printing the choice of screen ruling is determined by the paper upon which the illustration is to be printed, while fine screens (120 upwards) are generally used for photolithographic reproduction. The finer the screen, the finer the detail that can be reproduced but the smoother must also be the paper to ensure even tone.

The screen is held in the camera a few millimetres in front of the image plane, and light passing through the apertures formed by the lines exposes a dot formation.

Theory of Dot Formation. The penumbral theory (Clerc), suggests that the screen ruling casts a shadow, and that when the screen is at correct distance, the light is most intense at a point on the photographic material midway between two lines. Between these is an area of penumbra which is related to the intensity of light reflected from the original at any given point. If the original reflects little light, a small dot is built up; if it reflects more, the dot spreads. It is also suggested (Fruwith and Mertle) that the diffraction of light behind the sharp-edged opaque rulings contributes to the build-up of a graded dot.

Half-tone exposures in photo-engraving are adjusted so that a small isolated dot in the shadow areas, and a chessboard pattern dot in the highlight areas, is produced. The screen ruling, exact distance between the screen and the film, and the size (and shape) of the lens aperture must be carefully matched to obtain the correct dot formation.

For photolithography and for powderless etching processes in photo-engraving, it is necessary to expose for a formation of higher contrast. Normally these formations are obtained by giving a general exposure to obtain detail, and a "flash" exposure, using a small lens opening, to build up the density of shadow dots.

Contact Screens. These are on flexible material and are used in direct contact with photographic film. The screen elements are made up

DOT FORMATION WITH HALF-TONE SCREENS. Top: Cross-line screen. The screen, fitted slightly in front of the film, casts unsharp shadows on the film. Where light from highlights reaches the film the penumbra spreading into the intervals between the lines becomes bright enough to record on the emulsion as a large dot. In the shadows only the centre of the space is light enough to record as a small dot. The dots are sharp because the ultra high contrast film records no intermediate tone gradations. Bottom: The contact screen already has an unsharp dot pattern and is used in contact with the emulsion. A, screen. B, emulsion. C, support.

of variable density dots. Two types are available: neutral grey, and magenta. For direct colour separation grey screens must be used.

With magenta screens, contrast is controlled by using lights of different colour for exposing. A magenta filter over the light source decreases the contrast of the screen and increases the contrast of the image, while a yellow filter does the reverse. With grey screens, the contrast of result can be modified by using screens of various gradation, i.e., normal, bright, flat, or by varying flash exposures or development times.

Special Screens. Gauze and linen screens have been used to reproduce continuous-tone originals. These are wire, or bolting cloth, stretched taut, and used in the camera in the same way as a cross-line screen. Single line screens which break the image into parallel lines of varying thicknesses and screens with single wavy lines have also been used for special effects. Screens in which the elements take the form of grains have been used in the past, and there have been experiments with screens in which lines cross at 60°.

Relative Advantages. The cross-line screen has certain faults which affect tone reproduction. However, it is a traditional instrument, is easily used and is very suitable for conventional photo-engraving. The contact screen is less expensive, is easily stored. but may be damaged by grit, scratching or solutions. It is claimed that, because the contact screen is used in direct contact with photographic material, resolution

CC-0. Arunmugam Digital Preservation Foundation and Training

is higher than with cross-line screens. Further, contact screens can be designed to produce images with a specified tone range.

In practice, contact screens are used more frequently in photo-lithography than in photo-engraving, although it is considered that they are very suitable for making the negatives required for powderless etching and for photo-polymer plates. F.G.W.

See also: *Half-tone screen reproduction; Photomechanical reproduction.*
Book: *Photographs and the Printer*, by F. H. Smith (London.)

HALF-TONE SCREEN REPRODUCTION. When half-tone prints are to be reproduced by a half-tone process the prints must be re-photographed through a half-tone screen held in the camera in the usual way. Because of this, two uniformly distributed sets of dots, those of the print and those of the screen, are superimposed and a pattern, known as moiré, is created. It has been shown that if the dots coincided no pattern would result, but this is rarely possible, and precautions are always taken when re-screening to reduce moiré so far as is possible.

Several methods have been suggested, all of which involve diffusion of the image. A rough way of doing this is to focus the image so that it is slightly unsharp. Another is to focus the image sharp, but to vibrate the camera slightly and regularly during the exposure.

A more reliable method is to hold a piece of thick, clear film parallel to the front component of the lens and to vibrate this regularly during the exposure. Other suggestions have been to cover the original in the camera copyholder with a piece of matt film, or to substitute a grain screen for the normal cross-line screen in the camera when re-photographing..

Probably the most effective method is to place the original in the copyholder so that the lines of dots form an angle of 30° with those of the screen ruling. (A 30° separation is maintained in four-colour half-tone printing in order to reduce moiré). If a circular screen can be used in the camera this can be rotated to an angle which appears to reduce moiré to the greatest extent.

Optical apparatus has been designed to help solve this problem. Prominent is an anti-flare housing which fits on the lens panel and within which a rotating and rocking glass disc produces a controlled displacement of the image. The selection of cams to drive the glass is determined by screen ruling.

Optical tone filters are also designed to reduce moiré. On the surface of each filter, which is used in front of the lens, thin film discs of a coating (similar to lens coating) form a random pattern which deflects rays and produces a more continuous pattern out of the original half-tone dot pattern. Different filters have different proportions of coated and uncoated area. The choice of the correct filter depends upon magnification and the screen ruling of the original.

It is also possible to reduce moiré when reproducing half-tone proofs on a special electronic engraving machine. F.G.W.

HALOGEN. Collective term for the elements fluorine, chlorine, bromine, and iodine. Compounds of the latter three, with silver, form the main light-sensitive substances used in photography. Binary compounds of a halogen with another element—e.g., a metal—are known as halides.

See also: *Silver halide.*

HAND CAMERA. Name given to the types of camera that are normally used without a tripod —e.g., cameras for negative sizes of ¼-plate or smaller, with instantaneous shutters and focusing scale, rangefinder, or reflex focusing. The term was heard more often in the early days of photography when the stand camera was in more general use.

H. & D. SPEED. System of speed rating named from the initials of the surnames of two scientists, Hurter and Driffield. They collaborated in establishing the first generally-used system of measuring the sensitivity or speed of sensitized materials. The H. & D. system is based on the measured densities resulting from a range of exposures. The relation between H. & D. speeds is arithmetical—i.e., a film or plate rated as 1,000 H. & D. is twice as fast as one with a speed of 500 H. & D.

See also: *Speed of sensitized materials.*

HAND-OR-STAND CAMERA. Term, no longer in general use, describing a type of camera intermediate between the hand and stand types. It was usually a ¼-plate folding camera with rising and cross front and sometimes a small amount of vertical swing back camera movements.

In construction and purpose it was an attempt to bridge the gap between the two basic types. It was intended to be small enough to be carried unobtrusively and used for instantaneous exposures (therefore it was equipped with a shutter) and yet have enough of the features of the field camera to find favour with the serious photographer of landscapes and architecture, for which purposes it was equipped with a focusing screen as well as a focusing scale.

By and large the hand-or-stand camera never succeeded in satisfying either class of user and it is no longer made, although it is still occasionally listed in the second-hand market.

See also: *Camera history.*

HANDS. A hand is a very human and live thing and a photograph must reveal these

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

qualities or it will fail in its purpose. A great deal can be learned about the character of people by watching how they use their hands in everyday activities such as picking up a cup of tea, doing up a parcel and striking a match. The correct technique in photographing hands is to avoid a deliberate pose; the hands must be allowed to fall naturally into a relaxed position in character with the sitter. Hands are an essential part of a portrait, and must be made to fit into the composition in such a way that the eye sees the picture as a whole. A picture of a pianist, for example, should never give the impression that the hands were "placed".

While men are rarely conscious of their hands, women are more likely to be.

Distortion. The first and main aim in photographing hands must be to avoid distortion. This calls for a long focus lens and if possible a camera with swing back. The swing back is used to bring the plane of the hand as near as possible to the focal plane of the camera.

Lighting. Point source lighting—e.g., one or two 500 watt spots—is needed to bring out the contours and the texture of both men's and women's hands. The key light must be oblique and the shadow side filled in—e.g., with a diffused 500 watt flood. One spot and one flood are the minimum necessary. The fill-in light must be just strong enough to soften the hard shadows thrown by the key light, and no more. Where there is strong back lighting, care must be taken in balancing the lights or flare will occur on the edges of the fingers causing loss of texture.

When photographing men's hands the fill-in light should be only just strong enough to reveal detail in the shadows, while allowing sufficient contrast to produce a texture effect and perhaps even allow the hairs to stand out. With women's hands the fill-in light should be somewhat stronger so as to give a softer effect.

Special attention must be given to the background. Any surface that reflects highlights must be avoided unless the hands are actually engaged in working on a polished object, where such reflections are unavoidable.

Shadows. Great care must be taken to avoid awkward shadows cast by the fingers, which in extreme cases may give the impression that the sitter has four hands. In order to avoid shadows on the background the hands should be an appreciable distance away from it. With a back-lighted subject, the frontal fill-in light must be strong enough to kill the shadows cast towards the camera by the key lighting. There could, for example, be heavy shadows cast where a hand is resting on a book, which has been strongly back-lighted to bring out texture and provide modelling. Here the fill-in light could conveniently be improvised by using a small mirror to reflect some of the back light.

Hand Position and Camera Angle. Where hands are included in portraits they must never look posed, but at the same time it is necessary to pay attention to their angle in relation to the camera. The hands must be relaxed, with the fingers extended naturally. A view of the back of the hand with the fingers folding into the palm is ugly and meaningless. Hands should also neither be photographed with fingers extended towards the lens, nor so placed that the wrist is nearest the lens while the fingers point away from it.

It follows from the foregoing that unless a deliberately distorted view is required, unusual camera angles should be avoided.

Special Cases. When photographing a broad hand with the back presented to the camera, it is a good plan to place the index finger and the second finger so that they meet, making a division between these and the third finger—the third and fourth being slightly parted. This arrangement gives an impression of length. The lighting should fall at an oblique angle—at least 45° to the flat surface of the hand.

Where hands are to be clasped, intertwined fingers must be avoided at all costs. Occasionally the clasped hand is essential for certain effects—e.g., in dramatic poses. In such instances the technique is to take the left hand upraised—e.g., to the level of the chin—with the tips of the fingers of the other hand resting lightly in the palm, or vice versa. In lighting this arrangement, the key light for the face will provide adequate modelling without any additional lighting from the front, while the spread of the back-light—e.g., a 1,000 watt spot—will cover both head and hands, producing a strong feeling of depth.

Choice of Film and Paper. Medium speed panchromatic film is preferable for this work; processed in a fine grain developer it gives the desired amount of contrast. For printing, a glossy surface is preferable to the usual art paper, as a smooth surface does not conflict with the texture of the hands. Men's hands should be printed somewhat darker than women's. E.C.

Book: *Lighting for Portraiture*, by W. Nurnberg (London).

HANFSTÄNGL, FRANZ, 1804–77. Bavarian lithographer and portrait photographer. Established a lithographic business in Munich, 1834. In 1853 he opened a portrait studio and commenced photographic art publishing. His son, Edgar Hanfstangl, was the first to introduce pigment printing on a large scale in Germany.

HARDENER. Chemical—usually potash alum, chrome alum or formalin—used to toughen the gelatin emulsion (generally of films and plates, but sometimes of papers) to render it less liable to physical damage by scratching or rubbing.

Some hardeners may be incorporated in the fixing bath; others may be used as a separate bath after normal processing. Each has its own characteristics. The latter method is more

usually employed in special circumstances, for instance, processing cine films, etc.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

See also: *Hardening bath; Scratch-proofing.*

HARDENING BATH. High solution temperatures—above 75°F.—tend to make photographic emulsions turn dangerously soft or even melt and run off the support. So in hot weather processing, and also when using highly alkaline developers (e.g. the Meritol-caustic type), a hardening bath is essential. This may be used after the rinse or stop bath, or it can be combined with the stop bath. Some hardening solutions can even be used before development.

The most common hardening agents are chrome alum and potash alum. The former is more effective, but the latter keeps its hardening properties better in solution.

Formalin is also useful as a hardener, though its action on the gelatin is not of the same kind as that of the alum hardeners. Finally, tannic acid hardeners increase the actual physical hardness of the gelatin and can be used to make the film resistant to scratches and abrasion; they are only used after washing.

Chrome Alum. The simplest way to harden films or plates after development is to immerse them for about five minutes in a 3–5 per cent solution of chrome alum.

In hot weather, the solution should also contain about 10–15 per cent of sodium sulphate crystals (Glauber's salt) to prevent undue swelling of the gelatin.

All chrome alum hardeners (including acid hardeners and acid hardening fixers containing chrome alum) will harden as long as the solution looks purplish by transmitted light. When it starts to turn green, it should be thrown away. In acid solution the hardening properties disappear within a few days, particularly if acid sulphites are present. That is why acid hardeners (combined stop bath and hardener) and acid hardening fixers with chrome alum do not keep.

The presence of citric, acetic, and other organic acids also reduces the hardening action even of a fresh chrome alum bath. So negatives must be well rinsed between any stop bath and a chrome alum hardening bath.

An effective acid hardener (which is also a stop bath) consists of equal parts of 2 per cent solutions of chrome alum and potassium metabisulphite. This is best prepared just before it is needed, and discarded after use.

Potash Alum. Although chrome alum is the more effective hardener, potash alum keeps much better even though the solution must be acid to prevent precipitation of aluminium hydroxide by any alkali carried over from the developer.

A suitable potash alum hardening stop bath consists of a solution containing 2 per cent of potash alum, and 1 per cent each of sodium sulphite and glacial acetic acid.

A special potash alum acid hardener stock solution may be added to a plain hypo solution to convert it into an acid hardening fixer.

Formalin. A formalin hardening bath for use after development consists of 1 part formalin (40 per cent) solution diluted with 80 parts of water. The negative should be soaked in this bath for about 5 minutes.

Alkaline formalin hardeners are also useful before aftertreatment such as intensification, etc. The hardening is said to be more uniform than with acid alum hardeners, and there is less risk of uneven action of the solution used in the various aftertreatment processes.

A suitable solution contains 1 per cent each of formalin and sodium carbonate. Addition of about 10 per cent of sodium sulphate (Glauber's salt) prevents the alkali from swelling the emulsion. As the formalin takes some little time to harden the gelatin, a certain amount of swelling would otherwise be bound to occur.

Hardening Before Development. When processing at temperatures above 85°F. (30°C.) the films or plates are best immersed before development in a hardener of the following type:

Formalin solution (40 per cent)	1 ounce	25 c.cm.
Sodium sulphate, crystals	8 ounces	200 grams
Water to make	40 ounces	1,000 c.cm.

The material is immersed in the hardener for 3–4 minutes, rinsed in a 15 per cent sodium sulphate solution, and transferred to the developer. The hardened gelatin slows down the penetration of the processing solutions, so somewhat longer development is needed.

Chrome alum hardeners are not as suitable for use before development because they are definitely acid and thus reduce the activity of the developer. L.A.M.

See also: *Fixing; Hot weather processing; Scratch-proofing; Tropical photography.*

Book: *Developing*, by C. I. Jacobson (London).

HARDENING FIXER. Fixing bath, particularly one for fixing negatives, that contains a hardener so that the emulsion is hardened and rendered less liable to injury in subsequent washing, drying and handling.

Proprietary packs of fixer are usually available with and without the hardener.

HARD WATER. When developer is made up with hard water, the calcium and magnesium salts responsible for the hardness react with the sodium carbonate of the developer and precipitate a white deposit. (Although the sodium carbonate content is slightly reduced by the reaction, the amount is negligible.)

The precipitate has no undesirable chemical effects but it may settle on the surface of the emulsion and form clear spots or pinholes where it has prevented the developer from acting.

Calgon added to the water in the proportion of 1 gram to every litre of water prevents the formation of an insoluble precipitate. It has no

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ill effect on the working of the developer apart from increasing its alkalinity very slightly.

The deposit may also be removed by allowing the developer to stand until the milkiness settles and then decanting the clear solution.

In large-scale processing laboratories it may be worth while installing ion-exchange water softeners. Even small units can be fitted into the supply line at a suitable point.

See also: *Faults; Water.*

HARRISCOLOR PROCESS. An obsolete two-colour subtractive process for cinematography. Prints from colour-separation negatives are made on single-coated film printed first through the back, processed, and blue-toned with iron. The residual emulsion on the print is subsequently printed, processed and red-toned.

HAZE. Suspension of minute particles of dust and other matter in the atmosphere which scatters light and thus tends to obscure detail and degrade tones in distant views. The scattering is greatest for the blue component of the light and the red component penetrates the haze most readily; the haze itself therefore appears bluish, and its effect can be reduced by photographing the scene with a blue-absorbing —e.g., yellow, orange, or red—filter.

Haze is often of value in pictorial work by assisting in the differentiation of planes.

See also: *Fog (atmospheric); Mist.*

HEAT FILTER. Optical device for removing heat radiation from a light beam without appreciably affecting the light output.

The common sources of light used in projectors and similar apparatus emit a high proportion of their total radiation output as infra-red or heat radiation which consists of wavelengths greater than 0·7 micron. For example the proportion of the total radiation emitted as heat by tungsten projector lamps operating at 2800°K and 3400°K is approximately 94 per cent and 86 per cent respectively. For carbon arcs at 3800°K and 6000°K the proportion is 80 per cent and 48 per cent respectively. High-pressure mercury vapour lamps have a high luminous effeciency but still only emit 20 per cent as visible radiation, although the 1 kw. water cooled version will give 2½ times the light output with less than half the heating effect of a 1 kw. tungsten lamp. The xenon arc is similar in heat output to the carbon arc and has a group of strong monochromatic lines in the region 0·8 to 1·0 micron. Fluorescent mercury lamps with either hot or cold cathodes emit negligible infra-red, but are of limited use.

The heat radiation must be prevented from reaching the optical components and, in particular, the photographic image. Here the heat filter permits visible radiation to reach the optical system but absorbs, or otherwise diverts, the heat radiation.

Transmission Filters. The simplest heat absorbing filter is a thickness of water, about 1 cm., in a glass cell. This, however, only absorbs beyond 1·4 micron and so is restricted to low-temperature sources. The addition of 2 per cent by weight of copper sulphate ($CuSO_4 . 5H_2O$) to the water reduces the transmission limit to 0·8 micron but introduces a slight red deficiency in the transmitted light. More conveniently, heat absorbing heat resisting glass filters can be obtained. For example, a 4 mm. thickness of Chance type HR1 glass transmits a total of 82 per cent of the visible and only 7 per cent of the heat radiation from a tungsten lamp operating at 2854°K.

It is not possible with absorbing filters to obtain a sharp transmission cut-off on the long-wavelength side and, therefore, to obtain adequate visible transmission, some infra-red transmission must be allowed. Further, the absorbed radiation heats the filter causing a liquid one to evaporate and may cause a glass one to crack.

Mirrors. An entirely different type of filter, in principle based upon the interference of light waves, has ideal transmission properties. This filter consists of a multiple sandwich of alternate layers of transparent materials of high and low refractive index, deposited by evapora-

COLD MIRRORS IN PROJECTION SET-UPS. Top: *The lamp is backed by a light-reflecting but infra-red transmitting mirror. An additional heat filter in the light path protects the transparency.* Bottom: *An alternative set-up uses a normal metallized reflector behind the lamp, but an infra-red transmitting mirror in the light path to reflect the light through 90°. A, film or transparency. B, condenser system. C, heat filter. D, light source. E, cold mirror (infra-red transmitting, light-reflecting). F, fully reflecting mirror. The solid lines (shown as far as the first condenser) are light rays, the dotted lines infra-red radiation.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

tion upon a glass base-plate. The thickness of each layer is a fraction of a wavelength of light. Such a multiple layer can be designed to either transmit the visible and reflect the infra-red or vice-versa. The former is an infra-red mirror or heat filter and the latter is popularly known as a "cold" mirror or diathermic mirror. The transition from transmitting to reflecting is very rapid.

In use, an infra-red mirror is placed between the source and the optical system and a concave cold mirror used behind the source. Alternatively, light from the source can be reflected into the optical system, by a plane cold mirror placed at 45° to the optic axis. This has the advantage that no infra-red mirror is required and that the usual metallic concave mirror can be used behind the source. Multiple-layer mirrors of both types designed for normal incidence reflect 98 per cent and transmit 85 per cent of the incident radiation at the relevant wavelengths. The performance of those designed for use at 45° is not quite so good however.

Projection lanterns used for illumination are not usually equipped with heat filters with the exception of those used in photomicrography. Here it is often necessary to protect the speciment from undue heat.

The use of a heat filter of one type or another does not lessen the heating effects brought about by conduction and convection. These must be minimized by correct design and adequate cooling. G.G.T.

See also: *Diathermic mirror.*

HEAT RECORDING

While in most photographic processes the image is formed by light on a light-sensitive layer, thermo-sensitive systems can record images formed by heat radiation. This is useful for detecting objects in the absence of visible light, and also for establishing and measuring temperature distribution and differences in a variety of research applications.

Dectectors. An important element in any heat recording system is the detector. This is the device which converts the energy of the radiation falling on it into another form, which may be electrical, photographic or visual. Detectors are classed as either photon or thermal detectors.

The first type responds to the wavelength of the radiation and the second to the intensity of the heat source, ignoring the colour (spectral content). Both types of detector can be either image-forming, i.e. a real picture of the object is formed, or non-image-forming in which only a signal is produced. This latter method is widely used in military applications where the signal so obtained can be applied in a variety of ways, e.g. to control the movements of a guided missile. Only image-forming systems where a resultant picture is viewed or photographed are considered here.

Photon Detectors. In these the incidence of a small bundle of light energy (photon) on the detector releases an electron so that an electric signal, whose magnitude depends on the object being recorded, is available. Since these photons may be in the infra-red range they can be called heat rays. However in this class of detectors it is not the heating effect which forms a picture, but the photon effect; in other words, it is not the intensity of the heat which is important but its colour.

Examples of cameras and viewers of this type are the image convertor, the image dissector, the image orthicon, the vidicon and the metascope.

In the image convertor the infra-red (invisible) image formed on the photo-cell causes electrons to be accelerated down the tube. These electrons strike a phosphor film at the end of the tube and cause it to glow, giving a visible image. The image so formed is reduced in size and is upside down. A suitable viewer magnifies and erects the image or a camera can photograph it.

The image dissector is a television camera capable of providing a television picture using infra-red radiation. Because of fundamental limitations (noise—i.e. a high level of spurious signals not originating from the object) it has not been used very much in infra-red applications. This device, which is a scanning system, can be used in very low levels of illumination. Pictures can be obtained for scenes in bright moonlight. An image intensifier version of this device has been used to detect celestial bodies, such as the satellites of Jupiter, during daylight.

The metascope is a near infra-red viewing device. An infra-red lamp illuminates the target which is then focused by a mirror system on to a phosphor screen. This device is used at a wavelength of 1·3 microns. There are certain military applications for driving at night and it can also be used in signalling systems.

Thermal Imaging Detectors. These are of two main types—the evaporograph and the absorp-

IMAGE CONVERTER SYSTEM FOR MAKING INFRA-RED PICTURES VISIBLE. A, object. B, camera lens. C, image converter reproducing the infra-red image projected on the photo cathode as a visible image on the fluorescent screen. D, viewing lens.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

EVAPOGRAPH CAMERA. This consists of two evacuated chambers, one containing oil vapour and separated by a membrane having a layer of gold black. When an infra-red image is focused on the front of the membrane, the oil film deposited on its rear evaporates image wise, forming a picture which can be photographed through a glass window at the end of the oil chamber. A, evaporation membrane. B, infra-red transmitting sodium chloride window. C, vacuum line to pump. D, heating coils. E, absorbent pad of oil to keep the chamber saturated with oil vapour. F, conducting glass window.

tion edge image convertor. The evaporograph consists of a vacuum pump, cell, optics and camera. It relies on the evaporation of an oil film from a membrane on which an infra-red heat picture is projected.

The camera itself consists of a chamber that can be evacuated to a pressure of about 0·01 mm. The heat image is focused through an infra-red transparent sodium chloride window on to the black side of the membrane. The oil film on the membrane is evaporated from the warmer area of the image and condenses on the colder area, resulting in an oil film of varying thickness corresponding to the heating effect of the image. By optical interference this thin film of oil appears in various colours which are then photographed in the usual way by a camera and colour-sensitive photographic film.

The operation of the absorption edge image convertor depends on the fact that certain semiconductors, such as amorphous selenium, change their absorption and hence their transmission of light when locally heated. Any object which is even only slightly warm will, when focused on this selenium film, cause the film to transmit less light.

In a practical set-up infra-red rays from the object are focused by means of a parabolic mirror through the infra-red transmitting rock salt window on to the selenium film. This is 0·001 mm. thick and is backed with a chromium film to improve the absorption characteristics. Convection losses of heat are reduced by evacuating the chamber. The projected image heats the selenium film and decreases its transmission. This is observed by shining a sodium lamp via a mirror through the film and viewing the transmitted picture. Parts of the film which do not receive radiation will appear light yellow and the image itself will appear dark. It has been claimed possible to photograph a teapot in the dark at a considerable distance when the temperature is only about 60° C. It is even possible to image objects which are only 10° C above their surroundings.

Photographic Thermometry. When an object is photographed in the usual way using, say, panchromatic film, the negative shows a variation in brightness corresponding to the variation in brightness of the object. Using a densitometer, which will measure the transmission, one can measure the actual brightness of the object at various points, from the photographic information.

In the same way, it is possible to record the infra-red radiation from the object on infra-red film. In other words, the heat emissivity at various points on the object are recorded as corresponding density variations on the film. This, in effect, is photographic thermometry.

Fast infra-red film is used for the photography of hot objects in the dark to determine the temperature distribution over the surface, and studies of temperatures ranging from 250° C to 500° C are possible. The film should have a peak sensitivity of about 8,500 A. The hot object should not be polished but dark, and high-aperture lenses are necessary.

Colour Photography. Heat records on colour film are possible with temperature-sensitive paints when a minimum of apparatus is required. They give a record of surface temperature changes in the form of a pattern of coloured isotherms. A permanent record may be made by still colour photography or changes over a period may be recorded on colour film in a cine camera.

Certain paint compounds not only change colour at one temperature but change to various colours throughout a range. For example, a blue paint compound may change to bright green, then yellow and eventually to light brown as the object is heated.

Colour changes are also a function of time. Although the immediate effect occurs in one or two seconds, changes may continue for several hours. Exposure times of the order of ten minutes are required and it is possible with careful work to measure changes of colour equivalent to temperature changes of 10° C.

Pyrometry. This is the measurement of the temperature of a body by studying the nature of its radiation. Both optical and photographic techniques are available.

In optical pyrometry the human eye is the detector of radiation and relies on its ability to estimate degrees of brightness. The surface whose temperature is to be measured is viewed side by side with a source whose temperature is adjustable. Both the brightness and the colour of the comparison source are used to calibrate the temperature. The pyrometer consists of a telescope or viewer that shows the two sources alongside each other in a split-field eyepiece. The intensity and colour of the comparison source may be adjusted by rotating various colour filters and choppers in front of that part of the viewer which projects the comparison source, until a perfect match of colour and intensity is obtained. The rotation necessary is marked off on a temperature scale.

The job of the eye in the pyrometer may be

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

taken over by a camera. For low temperatures infra-red film is necessary since most of the radiation occurs in this range. For high temperatures (and pyrometry is concerned mainly with this), the furnace or hot object emits light which can be recorded by panchromatic film. The brightness of the light emitted by the body increases with rising temperature (although the two are not directly proportional).

The procedure consists of photographing tungsten-strip lamps burning at various calibrated temperatures. This photographic strip (which looks rather like a graded density wedge) is the master sample. The hot body is photographed throughout a range of exposure times and aperture stops.

Such a range of exposures is necessary because the exposure required for optimum density differentiation of temperature variations depends on the temperature itself. Hence a range of master samples, also exposed at different times and with different apertures, is used.

The densities of the negative are measured by standard photographic densitometric techniques. Comparison of the density of the test negative with the densities of a master sample strip exposed for the same time and at the same aperture then indicates temperature of the hot body. This technique can under favourable conditions estimate temperatures with an accuracy of plus or minus 3° C at 1500° C. It has been applied to the measurement of the temperature of furnace walls, hot metal ingots, welding methods, and—with certain modifications—of radio valves and superheated-steam lines.

Indirect Scanning Methods. Certain semi-conductors are particularly sensitive to temperature changes and greatly alter in their conducting properties as they get slightly warmer or colder. They are the basis of a number of industrial temperature measuring instruments. The most sensitive of them will also react to the radiant heat in the image of an object projected on the cell and can thus be used for infra-red or heat photography.

DIRECT PHOTOGRAPHY WITH HEAT SENSITIVE PHOSPHOR. A, camera with ultra-violet absorbing filter over lens. B, ultra-violet lamps. C, hot end of object. D, cold end of object. The ultra-violet radiation makes the phosphor glow, heat tends to subdue the glow. If photographed under suitably standard conditions, temperatures and temperature gradients can be determined by measuring the photographic densities of the object on the negative.

INDIRECT PHOSPHORESCENCE PHOTOGRAPHY. An image of a heated object with its temperature gradients is projected by a mirror lens on to a phosphor-coated screen irradiated by ultra-violet rays. The camera then photographs this image on the screen. A, camera. B, ultra-violet absorbing filter. C, paraboloid mirror. D, layer of phosphor on screen. E, heated object.

Such a recording system works in a manner analogous to a television link: it involves optical scanning of the object being examined or measured and reconverting the current fluctuations produced in the semi-conductor into signals that can reconstitute a picture. In practice a mirror optical system (which does not absorb infra-red rays like a glass lens) focuses an image of the object on to the photo-conductive cell. The optical system moves so that the cell scans the image from top to bottom and side to side like the image on a television screen.

The intensity of heat radiation from the object modulates the current in the cell circuit; this is amplified and in turn modulates the intensity of a projected light beam. The latter scans over a photographic film in synchronism with the scanning pattern of the mirror system in the "camera". The film thus records the temperature variations in different parts of the object as different densities. For instance, on the film warm subject areas reproduce darker than cold areas. The final black-and-white picture is made up of a series of closely spaced

CC-0. Agamnigam Digital Preservation Foundation (India)

lines, again like a television screen image. From this picture the surface-temperature distribution can be analysed with a detail resolution equivalent to the diameter of the scanning spot. This system is sufficiently sensitive to detect temperature differences as small as 0·02° C.

Systems of this nature have been used in various military and industrial fields, and even for medical purposes to detect differences of body surface temperature due to variations of the blood supply.

Heat Recording by Phosphorescence. Certain phosphors respond to ultra-violet light by radiating in the visible spectrum. For example the phosphor may glow yellow or red. It has also been found that the temperature of the phosphor affects the brightness which decreases rapidly with increasing temperature. So if an object is coated with such a phosphor and radiated with the light from a mercury arc it will glow yellow. If the object is gradually heated its brightness will drop. With a constant value of ultra-violet radiation, the brightness may change by as much as 10 per cent per° F and the light emitted lies in the photographic region.

The method is applied in two ways:—the phosphor may be coated directly on to the heated object or an image of the hot object may be focused on to a phosphor-coated screen.

The primary advantage of such a system is that it simultaneously shows a "thermal map" of the surface. For quantitative measurements of the heat distribution the photographic recording is analysed by densitometry.

For the projection method a large-aperture mirror optical system is required because of the relatively low output of the phosphors. The arrangement consists of an ultra-violet source, the mirror lens, a camera, and a filter to exclude ultra-violet radiation from the photographic film. It is possible to record an entire temperature pattern with one exposure. J.N.W

HECHT, WALTER D. Dates unknown. Austrian scientist. Collaborated with Eder in the production of the Eder-Hecht wedge sensitometer. This, when used with a standard quantity of magnesium ribbon as light source, was widely employed in sensitometry on the Continent until the introduction of the D.I.N. system.

HECTO-. Prefix used in the metric system denoting one hundred—e.g., hectogram, hectolitre. Little used in everyday practice.

HEGE, WALTER, 1893–1955. German photographer whose fine surveys of Naumburg, Bamberg and other German cathedrals in the late 1920s, and of the Athenian Acropolis and Olympia in the 1930s, are an important contribution to art history and the photography of architecture and sculpture. In 1930 Hege was appointed professor of photography at the art school in Weimar, but gave up the position in 1935 to devote himself entirely to photography and a number of art-historical and nature films. After World War II, Hege worked on art books and lectured on colour photography.

HELIOGRAPHY. Name given by Nicéphore Niépce to his photographic process for producing camera pictures and for copying engravings by superposition. The world's first photograph from nature was a heliograph of the view from a window at Niépce's house Gras, near Châlon-sur-Saône, taken in summer 1826. It was made on a polished pewter plate coated with bitumen of Judea, which hardens under the influence of light. After an exposure of about eight hours in the camera obscura, the parts of the bitumen which remained soluble were washed away with a mixture of oil of lavender and white petroleum. The result was a permanent direct positive picture in which the lights were represented by bitumen and the shades by bare metal.

In the case of copies of line-engravings, the plate could be etched and printed from.

HELIOTYPE. A modified collotype introduced by the London portrait photographer Ernest Edwards, December 1869, and worked in partnership with R. L. Kidd.

HELMHOLTZ, HERMANN VON, 1821-94. German physicist and physiologist. Photographed the solar spectrum, improved Brewster's stereoscope, contributed notably to the theory of colour and was partly responsible for the Young-Helmholtz theory of colour sensitivity of the eye. Biography by Königsborger (1902–3).

HENDERSON, A. L. 18??–1900. English photographer. Specialized in photoceramics and in background projection for theatres. For some years in the 1880s private photographer to Queen Victoria. Left a trust for the establishment of the Henderson Medal which is awarded by the Royal Photographic Society for the best papers on photographic chemistry or related subjects.

HENNEMAN, NIKOLAAS, 1813–?. Dutchman, one-time valet to Fox Talbot, who set him up as manager of the first photographic printing establishment, in Reading, 1843, and in a Calotype portrait studio in Regent Street, London, in 1847. In 1851, Henneman made the prints of photographs of the Great Exhibition for the illustrated Reports of the Juries.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

About 1857, his studio was closed down and in the 1860s he was employed in Oliver Sarony's studio in Scarborough.

HERSCHEL EFFECT. Ability of red or infra-red radiations to bleach out a latent image previously formed in an emulsion otherwise insensitive to this region of the spectrum. The effect is most marked with the pure silver bromide emulsion of certain development papers and in particular with those that contain an excess of soluble bromide.

HERSCHEL, FRIEDRICH WILHELM (SIR WILLIAM), 1738–1822. German astronomer living in England. Investigated (1800) the properties of the solar spectrum and discovered the infra-red rays. Devised means of measuring and recording infra-red. Biography by Sime (1900).

HERSCHEL, SIR JOHN FREDERICK WILLIAM, 1792–1871. English astronomer and pioneer photographic chemist, and independent inventor of a photographic process on glass (1839). Son of Friedrich Wilhelm Herschel. Coined the word "photography" (1839) and introduced the use of the words "negative" and "positive" as well as "snapshot". Discovered (1819) the thiosulphates and proposed in 1839 the sodium salt hypo as photographic fixing agent. Investigated the photochemical action of the solar spectrum. Discovered the different spectral sensitivities of the silver halides, chloride and bromide, and of silver nitrate. Discovered the Herschel effect, the name given to the fading caused by infra-red radiation falling on an exposed image, which has been the starting-point for much modern research on the nature of the photographic latent image. Discovered the bleaching effect of mercuric chloride upon the developed silver image, and the restoration by immersing such a bleached print in a solution of hypo; this is the basis of the mercury intensification process and also of the so-called magic pictures which produce an image when breathed upon. Herschel described the light sensitivity of the citrates and tartrates of iron and of the double iron-ammonium citrates. Invented cyanotype, the first blue print (1842). Also discovered and described the argentotype process, in which iron salts were used to precipitate silver under the action of light, and suggested microfilm documentation.

HIDE. Camouflaged screen or hut from which animals and birds can be photographed without the photographer revealing his presence.

HIGH CONTRAST DEVELOPER. Class of developers which are intended to produce images of higher contrast than normal.

HIGH KEY. All work in photography is based on tones—dark, middle and light. In normal work some of the tones from each group are used; the print thus ranging in tone from black, through the middle tones and the lighter ones to white. High key work is concerned with light and occasionally middle tones, leaving out the lower ones altogether. Only certain subjects are really suitable for this type of treatment.

The subjects that are best so treated are those which are to convey cheerfulness, lightness and delicacy, such as in portraiture of children and nudes, and in landscapes, atmospheric effects, early morning scenes and glancing light on water. It is wise to choose a subject which has no strong shadows, for full black is not going to be used. A high key print starts in the camera; it is not made by trying to turn an ordinary print into one of high key. It is dependent on lighting and subject matter. The ideal model for high key portraiture, for example, would have fair hair and a light skin, light blue eyes, and lightly made-up lips, and should be wearing light clothes.

Lighting. The lighting must be full and soft. For portraiture it is very necessary to have the subject in a light room with plenty of light reflected from all surfaces and a white sheet on the floor for the same purpose. There should be full frontal soft lighting from the direction

HIGH KEY TECHNIQUE. The elements in the production of a high key picture are: Top: Choose a light subject and light it softly to avoid heavy shadows. Upper centre: Expose for the highlights. Lower centre: Develop to a low contrast in a soft-working developer. Bottom: Print on a soft paper grade to preserve full detail in the highlights.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

of the camera and no shadows cast by the features, or they will photograph too dark. It is sometimes wise to place the lights so that one of the sources, quite near the camera viewpoint acts as a model light, casting some shadows. The remaining lights should then be placed so as very nearly to "kill" these shadows. They should not, of course, be permitted to cast counter shadows. Soft light is best obtained by allowing plenty of space between the lights and subject, for distance is a good diffuser. Diffusing screens of various types are also useful. Having obtained this result, it is then necessary to illuminate the background independently to raise its tone to either a shade lighter than the highest lights on the subject or a shade darker; the latter is usually best. If the background were left unlighted, even though white, it would photograph a mid-grey owing to its greater distance from the light source.

In daylight it is necessary to choose a day when conditions create a soft, diffused lighting, and the surroundings should help to give the feeling of lightness.

It is quite possible to use this type of lighting to give a high key effect to any suitable subject that demands the quality of delicacy and lightness, but in landscape work it is wise to wait for the right conditions—i.e., where the subject has no strong shadows. Misty, atmospheric subjects are the popular ones for such treatment, although against the light effects in mist treated in this way can be very satisfying.

Technique. It is essential to continue the special treatment through exposure and development. For work by artificial light, where all shadows have been reduced to a minimum, the exposure is not critical but should be fairly full. However, as there are no deep shadows to consider, full exposure for a high key subject is not going to be as long as that for a similar subject with a full tonal range.

Providing that enough exposure is given to produce a deposit of silver through the whole image, the type of negative wanted is largely a matter of personal preference. With outdoor scenes, however, it is desirable to give enough exposure to lighten any of the darker tones to avoid contrast.

In developing, it is essential to secure a softly-graded negative with all the highlight tones separated—a negative which will yield the soft, delicate print essential to high key reproduction. This can best be obtained by the use of a dilute developer.

More people fail in making the print than at any of the other stages. The correct procedure is to choose as soft a paper as possible and print it so that all the importance is on the highlight details while the darkest tone is no deeper than a middle grey. It is surprising how dark even this can look by contrast. The paper chosen should not, of course, be so soft as to make the print appear flat and dull overall. If the high-key print lacks sparkle, much of its purpose is lost.

The choice of paper base colour and surface can also make a big difference. A white base paper will enhance the general effect of delicacy; a cream base paper looks yellow and faded.

The aim in high key work is to achieve softness, lightness and delicacy, and all efforts must be directed to that end. D.A.

HIGHLIGHT EXPOSURE METER. Type of exposure meter that measures the intensity of the light falling on the subject.

See also: *Exposure meter.*

HIGHLIGHTS. Bright parts of the subject which are reproduced as the densest areas in the negative and as the lightest areas in the print or transparency.

HIGH SPEED CINEMATOGRAPHY

Motion picture recording at rates exceeding about fifty pictures (frames) per second, to photograph movement and events too fast to be perceived by visual or straightforward photographic methods. Such recording requires special means of operation, and high speed cinematography is accordingly classified as follows:

(1) High speed, at 50 to 500 frames per second, using intermittent film motion and mechanical shuttering;

(2) Very high speed, at 500 to 100,000 frames per second, using moving film and image compensation;

(3) Ultra high speed, at 100,000 to 10 million frames per second, using a stationary film with moving image systems;

(4) Super high speed, in excess of 10 million frames per second.

The boundaries between systems are not precise as some cameras employ combinations of techniques. This arrangement fits in with common practice in the main and also the terms used follow the same pattern as those used in the classification of radio frequencies although, of course, frames and cycles do not agree. It is unfortunate that superlatives were used too readily, that is, before the cameras in the last two groups became possible.

High speed cameras of group (1) are specially developed versions of normal cine-cameras, being limited in speed by the physical strength of the film, for the stresses imposed by starting and stopping between exposures can exceed the breaking point of the film base causing tears first at the sprocket holes. The fastest cameras operate at up to 300 f.p.s. on 35 mm. film and 450 f.p.s. on 16 mm. film.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

MOVING PRISM HIGH SPEED CAMERA. A rotating prism acts as shutter and keeps the image sharply in position on the moving film. 1. End piece of prism cuts off light. 2. Prism opens light path; image is displaced upwards by refraction. 3. The image follows the moving film. 4. After maximum downward displacement, the prism cuts off the light again.

In the cameras of group (2) the film is moved smoothly and continuously and some form of compensation is required to avoid image blur during the exposure.

In cameras of groups (3) and (4) the film is stationary and the image only moves.

Rotating Prism Compensation. Between the lens and the film is placed a rotating prism of regular form (parallel sided block, cube or octagon). By refraction, the light forming the image is moved during the exposure in the same direction and at the same speed as the film, the prism and film drives being suitably geared and driven from a common motor. Thus, during exposure, there is no relative motion between the image and the film. Suitable masks are fitted to the prism to limit the exposure time to the period during which compensation is possible. Masks with smaller apertures are also used when still shorter exposure times are required.

The physical strength of the film base again sets the limit and the maximum rates achieved are 20,000 f.p.s. with 8 mm. frames and 10,000 f.p.s. with 16 mm. frames. To maintain an economical camera life, it is common to restrict framing rates to 80 per cent of the maximum value.

Rotating Drum Systems. Some improvement in speed can be made at the expense of total recording time by attaching a length of film to a rotating drum so that the film now has support and the limit is set by the strength of the drum.

MULTIPLE ROTATING PRISM. Rotation of the compensating prism keeps the image stationary on the moving film as it passes over the sprocket. Successive frames are exposed as each prism surface faces the lens in turn. Prism and film movement are synchronized. Maximum camera speed is 10,000 frames per second on 8 mm. film.

Using a rotating mirror for image compensation, a commercially available camera gives 224 frames of 7·5 × 10·2 mm. at 26,000 f.p.s.

Using two concentric drums, one carrying the film and the other a number of lenses, frames of 5 × 8 mm. have been recorded at 40,000 f.p.s.

With a single objective lens and a rotating drum, it is also possible to synchronize a series of very short duration light flashes to the drum motion, so that the brief exposure of each flash is so short as to give no appreciable image movement. This permits framing rates up to about 100,000 f.p.s.

A complex installation of five drums and fifty spark gaps, all synchronized, produced 2,500 frames 25 × 20 mm. at 250,000 f.p.s. and 5,000 frames 25 × 10 mm. at 500,000 f.p.s.

Multiple-lens Cameras. To exceed the framing rates possible with moving film, various methods exist in which the image is moved along a stationary film.

The subject is imaged very near the surface of a rotating mirror (commonly about 25 mm. width). This image can then be re-imaged on to the film by an arc of lenses. A relay lens between the objective lens and the mirror images the stop of the objective on to the stops of the lenses on the arc. As the mirror rotates, the image-forming light beam moves from lens to lens on the arc producing a series of images on the film, with negligible image-to-film motion during each exposure. Exposure time of individual frames can be varied by changing the aperture stops.

Suitable mirrors can be rotated up to 80 per cent of their bursting velocity due to centrifugal forces, and when made of suitable materials, e.g. high tensile steel, rotation speeds of 500,000 r.p.m. have been achieved.

With individual frame sizes of 8 × 8 mms., all speeds up to 10,000,000 f.p.s. are possible. By changing the lenses used, larger frames at lower rates can be recorded using the same camera and mirror. The number of frames recorded is commonly between 30 and 200.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

ROTATING DRUM CAMERA. The film is fastened to the inside of a drum which further carries a ring of lenses, so that each lens covers one frame on the film. The image of the subject is projected into the centre of tho drum and from there directed to the circumference. As the drum rotates at a high speed, each moving lens picks up the image and keeps it stationary on the individual film frame behind the lens until the next lens moves into position. A stationary between-lens shutter cuts off the light after one revolution of the drum. A, stationary focal plane shutter (slit through which image is projected). B, final image, moves with film. C, stationary diaphragm shutter. D, moving lenses in drum. E, moving film in drum. F, intermediate image projected into centre of drum.

Use of two rotating mirrors and multiple reflections can produce still higher rates.

With a complex system of lenses, mirrors and prisms, combined with a rotating mirror, a form of focal plane shuttering can be achieved and is claimed to give shorter exposure times without loss of aperture.

To increase the number of frames in a sequence and to reduce synchronization problems, it is sometimes advantageous to keep the camera continuously recording. Thus irrespective of mirror position, an exposure is being made at all times somewhere on the film track. This can be accomplished by using multiple optical paths in one camera or by synchronizing two or more cameras together.

Adding a rotating drum mechanism to a rotating mirror system can increase the number of frames recorded without reducing frame rate excessively but the camera becomes more complex and expensive.

Many of these cameras do not produce records which can readily be projected as cinefilms, although skilful printing can make this possible. However when the number of frames is not large analysis is normally done frame by frame.

Capping Shutters. When photographing self-luminous subjects with high speed cameras which depend on polarized light (Faraday or Kerr effects) or on rotating drums or mirrors, a capping shutter is necessary if the luminosity continues after the camera exposure. Otherwise the image can record by polarizer break-through or extra camera revolution. Such capping shutters normally have to move from open-to-shut only, in periods around 10 microseconds. Less frequently, a shut-to-open system is required when the exposure is to be made after a period of luminosity or when the background lighting is high enough to record, say on a drum camera, by the additive exposure of many revolutions.

The methods used are numerous. They include the sputtering of lead wire on to a glass window by passing a high current through the wire; explosively spraying a black mixture (lamp black, say, plus a greasy binder) on to a window; explosively shattering a glass window sandwiched between two sheets of perspex such that it becomes relatively opaque by multiple scattering. Various tricks with very thin metal foils have been proposed which give opening or closing shutters depending on arrangement—all involve some electrical discharge circuit to produce the necessary energy, usually demanding many thousands of volts and large capacitors.

Passing a discharge through a thin metal layer forming a mirror, so removing the metal layer can also be used as either type of shutter.

Multiple Cameras. A series of pictures taken in sequence by a number of single-shot cameras constitutes a form of cine-photography. The advantages lie in the increased information per frame, flexibility in frame interval and exposure time, shorter exposure times and reduction of image movement.

An assembly of twelve Kerr cell cameras has been so used, each at 0·1 microsecond exposure.

ROTATING MIRROR CAMERA. The objective lens images the event via a relay lens on to the surface of the rotating mirror. The relay lens images the aperture of the objective lens successively on to miniature lenses which form further images of the subject on the film. Owing to the rotation of the mirror the reflected beam travels in the direction shown by the arrows, exposing successive frames. With two rotating mirrors the travel speed of the beam can be very greatly increased. A, film. B, miniature lenses forming final images. C, lens stops. D, objective lens with lens stop. E, relay lens. F, rotating mirror.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

MULTIPLE DRUM MULTIPLE SPARK CAMERAS. Each drum has its own lens and spark series. As each spark is imaged on the aperture of only one camera lens, it cannot affect the other four cameras. A, sparks. B, field lens. C, subject. D, drum cameras.

When triggered in immediate succession, this set-up can give a rate of 10,000,000 f.p.s. Kerr cell shutters have been operated at still shorter exposures down to 5 millimicroseconds (5/1,000,000,000 of a second). Similarly Faraday shutters and image tubes can be used.

For non-luminous events, a battery of cameras each with its own spark light source has been used at up to 100,000 f.p.s.

Some difficulty in analysis occurs in that these cameras all have slightly different viewpoints. To some extent this is overcome by using mirrors to bring the viewpoints closer. An alternative method is to make one camera with a sectional lens, that is, the lens is divided into segments which are then displaced a little from each other. Arranging a rotating disc with a single aperture causes each lenslet to be exposed in turn, giving a series equal in number to the number of lenslets. Such a camera, which is simple and relatively cheap, takes eight frames at 6,000 f.p.s.

Image dissection is also a kind of multiple exposure system, but with more complex recording and analysis requirements.

Optical Delay Camera. The extremely short exposures possible with a Kerr cell permit a further technique. The light from the subject is relayed to the camera via a system of mirrors such that six possible paths exist, all of different lengths. Light only travels 1 foot in 1 millimicrosecond. Thus, if the path length difference between adjacent cameras is 5 feet, then at exposures of 5 milli-microseconds, the light for one exposure is different from the light used in the next exposure. All six paths can be made to pass through the same Kerr cell, so that one shutter action produces six separate images corresponding to six separate time periods in the subject. Such pictures of exploding wires have been made at 5 milli-microsecond exposures and with frame intervals of 15 milli-microseconds, equivalent to 66,000,000 f.p.s.

Image Tube Framing Cameras. The shuttering and deflection properties of image tubes can be used to produce a short sequence of pictures on one tube. Image tubes can already be used to produce shorter exposures and higher deflection rates than other techniques and also can even intensify the light available making it possible to record events previously not sufficiently bright. A commercially-available camera gives three frames, each 17 × 25 mms., with exposures as short as 5 milli-microseconds at intervals of 50 milli-microseconds or 20,000,000 f.p.s. Other cameras give six or eight pictures at up to 1,000,000 f.p.s.

Timing. Cameras with moving film require timing marks on the film to assist in interpretation. In many applications the film never achieves a steady velocity and is often still accelerating when the magazine is exhausted. So small marks recorded at regular time intervals along the film edge indicate the film velocity (more precisely, the time resolution) at any point of the film. These timing marks can be produced by a variety of techniques which depend on some independent stable frequency source.

A tuning fork is such a source and its vibrations can be maintained by an electro-magnet powered by, say, a 12-volt battery. A ray of light shines via a slot mounted on the fork, the fork's vibtations causing the slot to interrupt the beam regularly, thus a 500 cycles per second fork produces 1,000 marks per second on the film; the camera rate is readily computed, e.g., 4 marks per frame—260 f.p.s., 4 frames per mark—4,000 f.p.s.

With the advent of transistors and miniaturization in electronics, quite compact units

HIGH SPEED CAPPING SHUTTERS. Top: In the shatter shutter a glass block is sandwiched between two perspex plates. At the end of the exposure an explosive charge shatters the glass and so obstructs the light. In the spattered wire shutter (bottom on the left) a high tension current pulse fuses a lead wire wrapped around a glass block in the light path. This spatters lead all over the glass, so obstructing the light. A, explosive force. B, light path. C, perspex plates. D, glass block. E, lead wire. F, trigger. G, high tension supply. H, high tension capacitor.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

OPTICAL DELAY CAMERA. The light from the event (from the subject) passes through a series of field lenses into an optical time delay tank. There it is reflected between a series of mirrors in the first and second mirror plane. It thus reaches the film plane of the camera at different instants separated by the time taken by the light to traverse different lengths of the optical path. This yields a series of successive images 1 to 6 on the film. A, subject. B, field lenses. C, first mirror plane. D, optical time delay tank. E, second mirror plane. F, Kerr cell shutter. G, 35 mm. miniature camera. H, film plane.

using crystal oscillators and dividing circuits to drive argon, neon or xenon lamps recording on the film through a narrow slit can be made. They have the advantages that the duration of the mark and its rate can be adjusted to suit requirements.

Particularly with cameras at rates below 1,000 f.p.s. a neat method is to include a clock (dial or digital) in the field of view so that, during projection, it can be observed at the same time as the record.

In the ultra high speed class with rotating mirrors, it is customary to direct a beam of light via the mirror to a path alongside the film where it can, by suitable masks, make marks on the film. Simultaneously the beam is received by a photo-electric tube which can then send out electrical pulses suitable for triggering events or light sources and for making measurements of the camera speed via electronic equipment.

Illumination. Up to 50,000 f.p.s., a variety of lighting systems are used including tungsten lamps, photofloods, flash bulbs and electronic flash tubes. A more sophisticated source is the pulsed xenon arc lamp which can be driven for short periods into peak powers of 10 kilowatts and produces enough light over an area of 1 square foot for photography at 20,000 f.p.s. on black-and-white film.

For higher framing speeds, many events are self-luminous but when subject lighting is required then either electronic flash tubes or argon flash bombs are used, which can be synchronized to the camera and the event.

Streak Cameras. In this special type of high speed camera a very narrow segment of the subject is selected for analysis and continuously successive exposures of this segment are made so that *all* visual changes during the recording period are observed. Thus the final photograph has exchanged one of its two space dimensions for a dimension in time.

In its simplest form, the subject is imaged by the objective lens on to a narrow slit thus selecting the portion to be analyzed. This slit-image is then re-imaged on to the film. The film may be attached to a rotating drum so that the slit-image is then streaked or smeared along the film at right angles to the long axis of the slit-image. The film could be moved past the slit-image by a camera such as a rotating prism camera, so giving a much longer record. Or again, the slit image could be moved along a stationary film by means of a rotating mirror to give higher writing speeds.

The writing speed of these cameras may be quoted in two ways, either the speed of the relative motion of the slit-image and film or by the time it takes for the slit-image to be moved by an amount equal to its own width. One is usually given in mm. per microsecond and the other in seconds or fractions of seconds. The latter is a better indication of performance and is the time-resolution of the camera.

The fastest rotating mirror cameras give writing speeds up to 40 mm. per microsecond (equivalent to 100,000 feet per second or nearly 100 times the speed of sound—Mach 100) with resolution times as short as $2{\cdot}5 \times 10^{-9}$ seconds (or 2·5 divided by 1,000,000,000). Rotating drums are unlikely to exceed supersonic peripheral speeds and so are at least 100 times slower.

Many streak cameras are not continuously viewing, hence it is necessary to synchronize the event to the period during which a record can be taken. By use of multiple optical paths within the camera, or multiple cameras, this can be overcome. A rotating element designed to achieve this with fewer components uses both refraction and reflection within a rotating element of twin prisms. As these must be transparent, only lower speeds can be used as the prism material will not have as high a tensile strength as metal mirrors.

Image tubes can also be used as streak cameras with relatively shorter recording periods. A slit-image of the subject is imaged on the photo-cathode. By electronic deflection within the tube, a streak image then appears on the screen. Such tubes have achieved speeds of 1,000 mm. per microsecond and resolution times of $0{\cdot}2 \times 10^{-9}$ seconds—1/5 of a millimicrosecond.

Claims have been made of resolution times approaching 10^{-11} seconds and the estimated limit is probably around 10^{-13} seconds. The time for light to travel one wave-length is only about 10^{-15} seconds, so it is apparent that absolute physical limits are being approached.

"Photo-Finish" Streak Cameras. One technique has been used which does not fit into either streak or framing categories but is somewhere between the two. If a streak camera is used to photograph a missile whose image velocity is equal to the streak speed, each portion of the missile will be photographed in turn and the film will show a still picture of the whole of the missile. This is a streak image of the changes in a given slit in space but is also equivalent to a very short exposure with a focal plane shutter.

It is also a high-speed version of the race-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

SIMULTANEOUS STREAK AND FRAMING CAMERA. A beam splitter divides the image rays from the objective lens along two paths to a rotating mirror. This in turn projects the images on the one hand through the imaging lenses of a framing camera, and on the other on to the film plane of a streak camera. A, objective lens. B, slit and beam splitting relay mirror. C, framing field and relay lenses. D, fixed relay mirrors. E, primary framing stop. F, streak camera field and relay lenses. G, rotating mirror. H, framing camera film plane. J, imaging lenses and secondary stops. K, framing camera projection lens. L, streak camera film plane.

track photo-finish camera. It is very useful in missile studies, as it can give a high-resolution picture of a missile in flight whose length is so much greater than its girth, where a more normal optical system could not.

Multiple-Slit Streak Cameras. If instead of a single slit, an array of parallel slits is used, a record sampling more portions of the event is obtained. The recording period is, of course, very much reduced, as the streak image of one slit should not overlap that of the next slit. Such a system, when the number of slits is large, becomes an image dissection system and operates as a form of framing or cine-camera.

Streak versus Framing Cameras. These cameras are not so much comparable as complementary. A framing camera records two spatial dimensions but only samples in time, thus it is possible for a change to occur between two frames which is not evident in either frame. A streak camera records one spatial dimension (i.e. a sample of space) continuously in time, such that no change in time within the space sample is missed.

The streak camera is ideal for studying events of uniform growth or decay, an expanding sphere or cylindrical discharge, when only the rate of growth is to be measured. But its results can easily be misinterpreted.

Combinations of framing cameras and streak cameras or streak cameras with a number of single shot cameras produce the maximum amount of information with the minimum possible errors and the minimum of equipment. One combined camera is commercially available giving up to twenty-three frames, 6 × 12 mm., at 8,000,000 frames per second and a streak record for 4·5 microseconds at 27·6 mm. per microsecond with a possible resolution time of 7·7 milli-microseconds.

Applications. Up to 20,000 frames/second, the subjects for high-speed cinematography cover a wide variety of fields in both industry and research including motors, relays, switches, textile machinery, internal combustion studies, rockets, biology and medicine.

At higher speeds, the uses are more likely to be in scientific research on explosives (both conventional and nuclear) plasma studies particularly for atomic energy fusion reactors, supersonic research for aircraft and missiles and studies of the fracture of materials, e.g., shattering of glass in car windscreens. HIGH SPEED PHOTOGRAPHY

Exposure times of mechanical shutters in still cameras generally have a shortest limit of around 1/1000 second. Photography with shorter exposures is classed as high speed work, and nearly always requires special techniques.

To arrest motion in a picture, either the shortest exposure possible is used or the camera is moved in synchronism with the subject (permitting the background to blur).

A formula for the optimum exposure time is:

$$T = \frac{L}{500 \times V} \text{ seconds}$$

where L is the largest subject dimension to be recorded and V is the subject speed in the same units as L per second. For example a car moving at 68 m.p.h. (100 feet per second) would probably have a longest frame dimension, L, of 50 feet. Thus $T = \frac{50}{500 \times 100}$ or T = 1/1000

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

second—just on the limit for a normal shutter and no camera motion.

It should be noted that both V and L determine the exposure time—increasing V or decreasing L both demanding shorter exposures. Many research subjects are both faster and smaller than a car.

Even an air rifle dart with a similar speed (100 f.p.s.) but only an inch or so long, according to formula and practice; requires an exposure as short as 2 microseconds (0·000,002 second).

The two main methods of taking high speed still photographs are the use of a suitable high speed shutter system, and the use of a short duration flash while the shutter is open.

High speed shutter systems may be magneto-optical, electro-optical, or electronic units using image converter tubes.

High speed flash systems may utilize electronic flash discharges or sparks, or special discharges such as X-ray flashes for high speed radiography.

Magneto-optical Shutter. This utilizes the Faraday effect, i.e., the rotation of the plane of polarization of light passing through a transparent medium in a magnetic field.

To use the Faraday effect, a suitable medium in a magnetic coil is placed between crossed polarizers. Dense flint glass is generally used, since it shows considerable rotation of the plane of polarization for a given magnetic field and is convenient to handle. With no current in the coil, there is no magnetic field, no rotation of the plane of polarization occurs and so no light is transmitted. When a suitable current is applied (often 1,000 amperes needing 10,000 volts) the plane of polarization is rotated until it agrees with the second polarizer, and the maximum light is transmitted. This current can be supplied by discharging a capacitor through the coil using a spark gap as a switch. The time of the discharge depends on the capacitor size, the voltage, and the number of turns in the coil. Exposure times down to 1 microsecond have been achieved.

In practice, a cylinder of the glass is placed in front of the lens and co-axially with it, together with the crossed polarizers, while the coil surrounds the cylinder.

ELECTRO-MAGNETIC (FARADAY) SHUTTER. A, first polarizer. B, light ray from subject. C, second polarizer. D, glass cylinder. E, coil. The second polarizer passes light only when the glass cylinder rotates the plane of polarization under the influence of the magnetic field. This is created by a high-voltage pulse passed through the coil.

ELECTRO-OPTICAL SHUTTER (KERR CELL). A, first polarizer. B, light beam from subject. C, second polarizer. D, electrodes in liquid cell. The liquid becomes birefringent on application of a high-voltage pulse to the electrodes.

The capacitor discharge may be controlled by a spark gap, the spark being in turn actuated by the subject itself (i.e., the shock wave or the flash from an explosion under examination).

Electro-Optical Shutter (Kerr Cell Shutter). Kerr discovered that certain mediums in the presence of an electric field become bi-refringent, that is, light polarized in one plane has a different velocity in the medium to light polarized in a plane at right angles.

The usual Kerr cell shutter consists of a glass cell fitted with electrodes and filled with nitrobenzene, and placed between two polarizers. The whole assembly may be mounted in front of the camera lens or within the optical system. The first polarizer is set such that its polarizing plane is at 45° to the cell plates and the electric field. Plane-polarized light entering the cell becomes circularly polarized, i.e. has two equal components each at 45° to the original plane of polarization, 90° to each other.

If a suitable voltage is applied to the plates (commonly near 20,000 volts), the phase difference produced by the differing velocities is such that on recombining at the second polarizer, the resultant plane-polarized beam is in agreement with this polarizer. With no voltage applied, no phase change occurs and the resultant beam is polarized such that no light is transmitted. Thus by switching the voltage on and off, a shutter is produced and exposure times down to a few thousandths of a microsecond (1/200,000,000 second) are possible.

Image Tubes. A variety of image tubes exist including image converters, orthicons, image-orthicons and image-intensifiers. Some of these can act as high speed shutters. Metals, particularly caesium, have the property that, in a suitable electric field, they emit electrons when irradiated with light. Also certain materials exist which emit light when bombarded by electrons (e.g. a television screen).

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

HOLST IMAGE CONVERTER. The main elements are: A, subject; B, lens; C, semi-transparent photo-cathode; D, electron stream; E, viewing screen observed by eye. As the image of the subject is formed on the photo-cathode the latter emits electrons. These travel through the evacuated tube and excite the fluorescent screen to produce an image there.

A combination of these into one evacuated tube can produce an image converter. The light receiver is called a photo-cathode, and the light emitter is the screen. An image is focused on the photo-cathode by a lens. By applying suitable electric and magnetic fields the image can be faithfully reproduced on the screen, which in turn can be photographed by a recording camera. With no voltage applied to the tube, no picture is produced. Thus by turning the electric field on and off, the tube acts as a shutter. The voltages employed are usually between 6,000 and 25,000 volts. In some tubes, other electrodes (grid electrodes) are inserted which can control the tube with lower voltages (e.g. about 300 volts). Additionally, by suitable electrodes or magnetic coils, the image on the screen can be deflected, permitting other techniques.

The orthicon or iconoscope uses as the light receiving element a mosaic of photo-emissive elements. These store an image which is later scanned off by an electron beam. The image-orthicon has a photo-cathode, similar to the image converter. The electrons from the cathode strike a storage plate which is again scanned later. An image-intensifier has a photo-cathode and a number of secondary-emissive surfaces, the electron beam passing from one to another in turn and being amplified before reaching either a screen or a storage plate. The gains possible in intensifiers, to date, are several thousandfold. An image converter can give some light intensification, e.g. at 25,000 volts, the light gain in a simple tube can be ten times.

Using image converters, exposures as short as 0·005 microseconds have been achieved, and it is in these devices, particularly, that further advances will be made. The physical limits are probably 1/10,000 of present results.

Flash Photography. The Electronic flash is now standard photographic equipment and is used not only when the available light is too weak but, with an open shutter, to arrest motion due to the shortness of the flash. Normal photographic electronic flashes have durations in the region of 100 to 1,000 microseconds, which is too long for most high-speed subjects. But with special tubes, capacitors and high voltages (7,000 volts and more), durations of a few microseconds or so are quite possible.

As the exposure time gets shorter, the brightness of the light source must increase. The threshold of fast films has been measured at very short exposures to be 10^{-3} metre-candle-second. This means, allowing for all the likely losses, that the subject illumination needs be about 1 metre-candle-second or 1,000,000 lumens per square metre for 1 microsecond, equivalent to a source of 1,000,000 candles at a distance of 1 metre.

The light sources capable of producing such high levels normally used in high speed photography include special electronic flash tubes, sparks and flash bombs. Sparks are produced by capacitor discharges across tungsten, steel, or copper electrodes. They have been made with durations as short as 7 millimicroseconds (7/1000 microseconds). In the microsecond region, an improved spark gap has argon gas blown into it via a hole drilled along the axis of one electrode giving a longer gap for the same voltage, more light output and a repeatable line source suitable particularly for schlieren photography.

A special type of spark is obtained by the explosion of thin metal wires. The wire is connected in series with a spark gap, wired in parallel with a bank of capacitors. These are charged to 15,000 to 60,000 volts. As the voltage rises, the spark gap breaks down, and the wire explosively vaporizes with a brilliant flash. Generally, however, explosions are more likely to be events studied by high speed photography than light sources for other subjects.

High speed radiography units have been designed for exposures as short as 0·03 microseconds. A high vacuum X-ray tube is used for the purpose and is fed by 500,000–2,000,000 volt pulses at several thousand amps.

Flash bombs are tubes containing argon with a transparent end-window and a small explosive charge at the opposite end. The explosive, when detonated, produces a luminous shock-wave in the gas which produces a high light level for

IMAGE CONVERTER SET-UP. This system is used for single photographs of non-luminous objects which are illuminated by a flash tube. The image converter shutter is synchronized with the peak of the flash. A, electronic flash tube powered in the usual way. B, trigger circuit. C and E, variable delay circuits D and F, thyratron switches. G, lens. H, image converter

CC-0. Agamnigam Digital Preservation Foundation Chandigarh

periods from fractions of a microsecond up to many microseconds, depending on the geometrical structure.

The latest light source is the giant pulsed laser, giving extremely energetic flashes as short as 30 milli-microseconds, concentrated in a very narrow spectral band and in a very parallel beam. It allows photography of the surfaces of other highly luminous surfaces as the subject light can be ignored by a narrow-band filter set to accept the laser light only.

With these various devices, high speed still pictures can be taken, using normal cameras with open shutters, always assuming that the background light level is not excessive.

Stroboscopic Operation. Using a still camera and a flashing light source (stroboscope) a subject can be photographed in a series of positions in one picture. Alternatively, by synchronizing the flashes with a subject with a repetitive motion, a succession of exposures can be superimposed of the subject in the same position.

The first method, with the flashes at regular intervals, is useful in studying movement sequences (e.g. athletes, dancers, etc.). The second method serves to study mechanical motion when it is not possible to produce enough light to take a single short-duration exposure or when it is desirable to check that the subject is truly repetitive. Stroboscopic flash units are available at speeds up to many thousand flashes per second in some special cases, but more commonly operate at around 100 per second.

Lighting Technique. High speed photographs taken with electronic or optical shutters need a high level of illumination. Self-luminious subjects, such as flash discharges, explosions, etc., usually themselves provide sufficient illumination for high speed photographs. Non-luminous subjects, as well as those where the self-illumination is not to be recorded, must be lit up separately. There the light source may be either a constant-intensity lamp, or a flash unit synchronized with the shutter.

Suitable constant-intensity sources are high pressure mercury vapour lamps. They are available in units up to 1,000 watts, with an arc length of about ½ in. With an appropriate reflector, lighting levels up to 50,000 foot-candles can be achieved over an area 5 ins. in diameter, 8 ins. from the lamp.

Pulsed xenon arc lamps can reach light intensities ten times as high. The lamp usually burns at 50 watts, and is pulsed up to 10,000 watts for periods of 2–3 seconds.

In many cases the high instantaneous intensity of electronic flash or spark units makes them more suitable as high-speed light sources, even when an electronic or optical shutter is used. The light usually still lasts longer than the effective shutter opening, so that the latter controls the exposure time.

The light may be synchronized to the shutter so as to provide the whole of the illumination, or merely the shadow illumination for self-luminous phenomena such as explosions. Alternatively, the synchronization may be timed in such a way as to exclude the self-light of the phenomenon (e.g., explosion flash) and record only the movement of, for instance, the shock wave. This procedure is possible only with the aid of a high speed shutter. Such a shutter is also useful for eliminating other extraneous light. That may include the "tail" of the high speed flash discharge itself; even a 2-microsecond discharge takes about 15 or more microseconds to die away completely. Such a comparatively low intensity light may, without a Kerr cell or similar shutter, record on the film owing to its duration, and blur or obscure the main subject.

Synchronization. It is equally important not only to select the correct exposure time but also the correct exposure instant. Various techniques are possible and each new experiment may suggest or demand a new method.

When the event is self-luminous, a photoelectric trigger is most commonly used. It has the particular advantage that the trigger sensitivity level can be so adjusted that the exposure is not made until the subject is sufficiently bright to be recordable. For exposures at later instants, the same trigger may be used and electronic delay circuits inserted before a start signal is passed to the shutter.

Should the event and the camera both be capable of precise triggering, suitable signals can be generated from a common source thus allowing any possible time arrangement to be selected. An important factor is to know the response time of all components. This becomes increasingly important as time intervals get shorter, reaching eventually conditions in which it is essential to make due allowance for the transit time of light. In one nanosecond (0·000,000,001 second) light only travels approximately one foot.

When the event is non-luminous, some light source is necessary. Especially at the shorter exposures this is some form of electrical discharge started by an electrical signal. The event must then be made to activate some electrical circuit and in a sense be made to take its own picture. For example it can be arranged that a light beam to a photocell is interrupted, a projectile can break a wire or pierce a screen to give a signal. At lower speeds, relays can be used. Each subject usually suggests its own solution.

On supersonic projectiles or events initiated with a bang, an acoustic pick-up can be a very elegant device. For example, when photographing the action of guns and their projectiles, a pick-up to detect the initiating explosion or the projectile's shock wave can be used to start the light source and, when necessary, the shutter. Merely moving the pick-up along and

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

below the line of flight can trigger exposures at different instants, by knowing the lines of the pick-up was moved and comparing it with the change in the projectile's position in the pictures, the projectile's velocity can be readily given as a multiple of the speed of sound.

More elaborate arrangements are sometimes required, including, for example, coincidence circuits when two parts of an experiment are not precisely controllable. But normally relatively straightforward optical, acoustic or mechanical devices will suffice.

Applications. High speed still cameras have been used in almost every field of scientific and industrial research, permitting the study of subjects whose changes are far too rapid for the unaided human eye. It is true that it is in weapon research that most advances have been made but it is one of the bonuses of warlike activities that high speed photography has been developed to its, already, very high standard and that it is now available for more peaceful ones.

It has been a valuable tool in the studies of motors, complex mechanical processes, medicine and the peaceful uses of atomic energy.

Exposure Effects. Exposures of short duration at high light intensities are subject to reciprocity failure. The effective sensitivity and contrast of most materials reaches a minimum around exposures of 10 microseconds. Below that the reciprocity law is usually valid, and the sensitivity of blue-sensitive emulsions remains independent of the exposure time. With optically (dye-) sensitized emulsions a further loss of speed occurs around 1 microsecond exposures, and is believed to be due to the sensitizing dyes. Above 10 microseconds the speed and contrast increase, showing a maximum at 10,000 microseconds (1/100 second). This is generally the optimum exposure time from the point of view of speed for most materials.

HIGH SPEED PROCESSING. Special formulae and techniques enable negatives and prints to be processed in an extremely short time. High speed processing is used principally: in photofinish race recording, when a finished print can be produced less than two minutes after the photograph was taken; in newspaper offices and picture agencies, for dealing with urgent topical news photographs; and in hospitals, where medical X-ray photographs are often processed at high speed to show the results of an operation. Instrument recording cameras may incorporate high speed processing features for immediate access to results.

HILL CLOUD LENS. Camera lens designed by R. Hill for photographing cloud formations over the whole sky; the camera therefore has to cover an angle of 180° with the lens pointing vertically upwards. Any surrounding vertical objects such as trees appear on the plate laid out in a radial direction. Distortion is corrected by using the same camera as a projector, with the image on the developed plate projected on to a hemispherical screen. In the lens a moderately wide angle lens (covering about 60°) is placed behind the stop, and in front is a negative meniscus component, arranged such that an object field of 180° is compressed into the smaller (60°) field of the rear element.

HILL, DAVID OCTAVIUS, 1802–70. Scottish painter and photographer. He was the first to demonstrate the artistic potentialities of photography. In 1843 he decided to paint the first General Assembly of the Free Church of Scotland.

This involved a total of some 470 portraits of delegates and it was to assist him in this task that he called in the aid of calotype. This was in collaboration with Robert Adamson, who was recommended to him by Sir David Brewster. The collaboration lasted until the illness of Adamson in 1847, and to this period belongs the best work Hill did.

It is generally conceded that some of his portraits comprise work which has never been excelled.

Biography by H. Schwarz (English translation: London and New York 1932).

HINE, LEWIS WICKES, 1874–1940. American sociologist who took up photography in 1905 to illustrate his work, documenting the miserable lives of poor European immigrants, and of Pittsburg iron and steel workers, 1908. As staff photographer to the National Child Labour Committee, Hine exposed in 1911, shocking conditions which contributed to the passing of the child labour law. During and after World War I he worked for the American Red Cross.

Hine also made a photographic record of the erection of the Empire State Building, in New York, 1931.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

HIRE PURCHASE. Hire purchase trading in Britain is regulated by the Hire Purchase Act, 1938, the short Act of 1954 and regulations made from time to time by the Board of Trade under emergency powers. The Act now applies to all hire purchase transactions in photographic or other goods in which the hire purchase price does not exceed £300 (not £100, as prior to August, 1954.) Further, the Advertisements (Hire Purchase) Act, 1957 lays down certain minimum information which must be included in all advertisements to which this Act applies wherein goods are advertised as being available on hire purchase or credit sale.

Under a hire purchase agreement goods are hired to the customer who is granted an option to purchase, which is taken up when he completes the last payment. Until that last payment is made the goods belong to the dealer.

Terms. The extent to which hire purchase terms are available on photographic goods is increasing and a large number of dealers now offer them. The terms vary. The majority of photographic dealers use those recommended by the Photographic Dealers Association to its members, namely a deposit of 50 per cent of the hire purchase price with interest on the balance of 5 per cent for nine months, and 7½ per cent for longer than nine months. Legal minimum requirements laid down in June, 1962 are a 10 per cent deposit, and balance payable in not more than three years.

Very few photographic dealers will offer hire purchase terms on goods priced below £5 or will extend the payment period beyond two years. Instalment payments are usually made either monthly or weekly.

The financial status and stability of an applicant for hire purchase terms are of utmost importance to the dealer. It is usual to present the would-be purchaser with a proposal form for signature, and for details of his residence, occupation, etc., and banker's reference.

The Agreement. In the case of goods to which the Act applies, a hire purchase agreement must be entered into—over the signatures of the dealer (called the "Owner") and the customer (called the "Hirer").

Before the agreement is signed the Owner must declare in writing, to the prospective Hirer, the cash price of the goods. The agreement itself must contain the cash price, the hire purchase price, the amount of each instalment and when payable, and a list of the goods to which the agreement relates, sufficient to identify them. If the goods are second-hand, this should be stated so as to avoid the statutory implication that they are of "merchantable quality". Further, the agreement must contain a prominent notice in the terms prescribed by the Schedule of the Act, which sets out:

(1) The right of the Hirer to terminate the agreement at any time before the final instalment becomes due (subject to certain conditions of payment to the Owner).

(2) Restriction of the Owner's right to recover goods from the Hirer, without his consent, once the Hirer has paid one-third of the hire purchase price. If that has been paid the Owner may only recover the goods by obtaining an order in the County Court.

Finally, once the agreement has been signed, a copy must be sent to the Hirer within seven days.

(Agreement forms, printed and detailed, which, when filled in and signed, conform with all provisions of the Hire Purchase Acts, may be obtained ready printed.)

Method of Financing. The method of financing the hire purchase system of trading is important and must be considered carefully by the dealer. He may finance it himself or enlist the services of a finance house. If he finances the deal himself, he will require an amount of extra capital which may be considerable. The custom with some dealers is to finance the smaller transactions themselves and to hand the bigger deals to a finance house. The finance houses operate various methods, but dealers usually prefer an arrangement in which they sell the equipment to the finance house who then hires or sells it to the customer. Where this arrangement is used, the finance house, under its agreement with the dealer, usually has a right of recourse against him if the customer defaults. A.F.A. (A.J.W.)

American Practice. Hire purchase is much more widespread in the U.S.A. (there known as time payments). Terms are not so closely controlled by law, and vary throughout the country. General terms, subject to a thorough credit investigation of the purchaser, are: 10 to 20 per cent deposit, with the balance payable over 3 months to 1 year. The interest charge is about 6 per cent on the unpaid balance.

Many dealers do not finance the sale themselves; once their bank or financing agency has approved the sale, they receive the full purchase price from that bank or financing agency. The latter then collects the monthly payments from the purchaser.

HISTORIOGRAPHY OF PHOTOGRAPHY. The first task of any history of photography is to relate technical progress. Beyond that it has to take note of the men who use the techniques and the work they accomplish. The history of photography is also a history of photographers and photographs. Side by side with the technical record unfold the stories of photography as an industry and as an art form.

Technical progress in photography stems from three sources: chemistry, optics and engineering. Whenever developments from one angle overtake the others a new challenge ensues for advance all round. This pattern of technical interactions is complex enough to discourage professional historians. Histories of photography are, as a rule, compiled by students of photography who, as historians, are mostly amateurs.

CC-0. Agamnigam Digital Preservation Foundation, Chennai

As photography is not much more than a century old a fair amount of source material is accessible, some of it still unpublished or just waiting to be discovered. Old photographs and historic equipment offer self-documenting evidence and confront the student with *embarras de richesse*. There are but few safe short cuts of organized basic information; what we have of contemporary or near-contemporary writing befogs rather than illuminates the origins and decisive turns of the art. The historian, being forced to accomplish first a great deal of original field research, is in danger of getting prematurely exhausted and myopic. Unskilled or limited research is easily satisfied with its own results and proceeds to vest its guiding interests in them; dates and names that are but pegs on which to hang a tale will then be mistaken for the whole story.

Thus histories of photography are sometimes bogged down at elementary levels; the assembling of data and cataloguing them according to controversial priorities. Preoccupation with details is more frequent than constructive integration of available knowledge, or imaginative interpretation of trends.

In particular, insufficient attention has so far been paid to cause-and-effect relationships between technical changes and modes of picture-making. The rejuvenating impact of advancing photographic tools—which steadily broaden the photographer's view of his subject matter and periodically vary his methods of pictorial articulation—awaits much study. Short of it, any grand synthesis of the history of photography is difficult to conceive.

Component histories of lenses, sensitized materials, cameras, etc., are more easily assembled although still not always simple to follow. It is a weakness of specialist historians to delight in expounding subtle distinctions or to overstress freakish phenomena—neither of which is, as a rule, relevant to normal developments. Yet this is not over-important.

The historiography of photography is badly in need of more scholarly monographs, dispassionate biographies and thoroughly researched local and national histories. The immediate task of new historians lies in this sphere of working to limited objectives and presenting balanced views of specific areas rather than in staking comprehensive claims of coverage based on incomplete or uneven material. A.K.-K.

Newall (New York); *The History of the Discovery of Photography*, by G. Potonniée (New York): *The March of Photography*, by E. Stenger (London).

HOFCH, EMIL VON. 1865–1915. German lens designer. Calculated in 1892 one of the most important modern lens systems, the symmetrical double anastigmat, manufactured by C. P. Goerz, Berlin, and later named Dagor.

HOLD-ALL. Leather, fabric or plastic carrying bag—usually fitted with a shoulder strap—designed to take the whole of a photographer's equipment of camera, exposure meter, interchangeable lenses, filters, lens hoods, spare films, etc.

See also: *Cases.*

HOLDING THE CAMERA. Blur caused by camera shake is one of the commonest faults in negatives exposed with the camera held in the hand. This is understandable because most amateur snapshots are taken with shutter speeds of 1/25 and 1/50 second. Most people think that they can hold a camera steady for such short intervals. But actual tests show that shake is common at all shutter speeds up to 1/150 second. Even so, it is fairly easy to learn to hold a camera steady at 1/25 second.

Gripping the Instrument. The exact way of getting hold of the camera body will depend on the type of the camera used, on its size relative to your hands, and on personal preference. The grip to aim at in every case is one which permits pressing of the release—and operation of other essential controls, e.g., rangefinder focusing knob where appropriate—without detracting from the support which the hands should give the camera. This is often a matter of trial and error; try different holds and see how comfortably you can release the shutter while still holding the camera still.

Cameras with eye-level finders are best pressed against cheek and forehead for steadiness, with the hands gripping each end of the body. With a folding model, the fingers of one hand may, if there is room, curl round one side of the baseboard, or else be tucked behind it. In either case, keep all fingers clear of the lens and rangefinder windows (if any). If the camera is in an ever-ready case, use the third and little fingers of one hand to keep the lid or flap of the case out of the way of the lens when necessary.

A camera strap (or the strap of the ever-ready case) can increase steadiness, too. For that purpose, shorten the strap until the camera lies well up on the chest with the strap hanging round the neck. Then bring the camera up to the eye, and hold it so that one or both hands are inside the loop of the strap. A certain amount of outward pressure will then tension the strap and keep the camera firmly pulled against the face.

The normal hold for a camera with waist-level finder—box cameras as well as reflex models—is to press it against the chest keeping both arms and elbows close to the body. If the camera or case has a neck strap, it is again

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

CAMERA HOLDS AND STANCES. 1. Normal horizontal hold for camera with right-hand release button. 2. Vertical hold (for upright pictures), using the thumb to press the release button. 3 Alternative vertical hold, derived from the original horizontal position. 4. Twin-lens reflex camera on a short strap round the neck. 5. The camera should still be steadied by the hands. 6. A table will serve as a support for steadying the hands while holding the camera at slow shutter speeds. 7. Leaning against a tree for support. 8. Floor-level camera position.

useful to shoot it so as to bring the camera up as high as possible for comfortable viewing. Pulling against the strap will aid in holding the camera steady.

Finally, release the shutter smoothly. To do this you must practise until your finger can take up the first idle motion of the release quite quickly, and then squeeze steadily until the shutter trips. Do not try to release the shutter with one sharp movement or you will amost certainly jerk the camera. Aim at maintaining a uniform pressure throughout, without worrying about when the actual release will occur.

Supports. When making a fairly lengthy exposure, look around for something to brace your body against or rest your elbows upon. By using a tree, the side of a building, a lamp post, the top of a car or a gate, you can greatly reduce the risk of camera shake from the start. It is even better if you can hold the camera itself against something solid like a tree or lamp post.

If you are forced to work without some such support, go down on one knee and brace your elbow against the other, like a marksman. If this is impossible, or if it results in an unsatisfactory viewpoint, then at least stand with your feet well apart and your heels flat on the ground.

Breathing. Some people find it easier to breathe out and then release the shutter, others breathe in and release the shutter while they hold their breath. Both of these methods lead to trouble if you have to wait before you make the exposure. The best way is simply to breathe naturally throughout the release.

Finally, waste no time over the operation. Do not prepare to release the shutter until you are quite ready to shoot, then proceed without hesitating. If you spend needless seconds at the ready you will stiffen up, start worrying about camera shake, and inevitably produce it.

HOLLAND. Photography was originally introduced into Holland by itinerant exponents of the daguerreotype, and there are several good specimens of their work in private and official collections. Since that time the growth of photography has kept pace with that in other European countries in the scientific, professional and amateur fields. The popularity of photography in Holland owes a great deal to the use of the camera to illustrate the country's vast amount of public and private contact with overseas.

Science and Industry. Dutch scientists have made a number of important contributions to photographic progress—principally in the optical field. The invention of the microscope by Zacharias Janse of Middelburg in 1590 and of the Dutch telescope by J. Lippershey of the same town in 1608 can both be regarded as essential preliminaries to the optics of photography. Snellius, a professor of Leyden, discovered the laws of refraction in 1625 or earlier,

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

and in 1678 the famous Dutch scientist Huygens, originated the wave theory of light.

In recent years Prof. Dr. A. Bouwers has made further contributions in mirror optics and wide screen cinema projection, while the popular Albada viewfinders are the invention of the Dutch optician. General L. E. W. van Albada, who also made remarkable discoveries in wide-angle stereophotography.

The Universitaire Film (Academical Film Centre) at the University of Utrecht has an international reputation in the field of medical cinematography.

In industry Holland has one manufacturer of sensitized materials—roll films, printing papers and X-ray films—and photographic chemicals. In addition there is a world famous organization in Eindhoven which exports flash bulbs, studio lamps of all kinds, and cinematograph projectors for both 16 and 35 mm. films. This great industrial concern has also been closely concerned in the development of the electron microscope and its application to scientific and industrial problems. The best-known Dutch optical firm at Delft is famous for its optical mirror systems and has produced a new wide-screen method for cinematography without chromatic aberrations—of importance with colour films. They also make equipment for mass miniature radiography for export.

Holland has several small factories making screens, and various small pieces of equipment. At Utrecht there is a famous factory making microscopes, and at Venlo glass is produced. Several manufacturers of colour films have their own processing laboratories in the country.

Holland is a very photo- and film-minded country, and imports of equipment and materials are considerable. By far the highest total percentage of all imports at present are from Belgium and West Germany. The U.S.A. leads in imports of 8 and 16 mm. colour cine-films.

Organizations. There is the Nederlandse Vereniging voor Wetenschappelijke Fotografie (Netherlands Society for Scientific Photography) which is associated with the International Scientific Film Association, and the Nederlandse Vereniging van Fabrikanten en Importeurs van Fotografische Producten (Netherlands Society of Producers and Importers of Photographic Products). The retail trade has its own Bond Nederlandse Fotohandelaren (Society of Photographic Dealers) and the professional photographers are organized under the Nederlandse Fotografen Patroonsvereniging (Society of Master Photographers). The Nederlandse Fotovakschool (Netherlands School for Professional Photography) is the only educational institution authorized by the Ministry of Education to hold examinations and award qualifications in technical and commercial photographic subjects. Press photographers also have their own professional organization.

The various trade associations organize joint propaganda drives, using instructive cinema films—e.g., to promote the sales of cameras and flash equipment.

The Dutch Society of Press Photographers holds an annual World Press Contest at the Hague. Entries of press photographs from all over the world are exhibited on this occasion, and high cash prizes awarded to the winners. The first prize is £1,000 and a free trip to Holland for the occasion.

In the University of Leyden, part of the Rijks Prenten Cabinet (Government Print Collection) consists of the famous "Gregoire" collection of daguerreotypes and historical photographs.

The amateur movement in both still and cine photography is very strong. There are 110 camera clubs in the Bond van Nederlandse Amateur Fotografen Verenigingen (Federation of Dutch Amateur clubs), while sixty-six amateur cine clubs are united in the Nederlandse Organisatie van Amateur Film-clubs, or N.O.V.A. (Netherlands Organization for Amateur Cine Clubs).

The Nederlandse Amateur Fotografen Vereniging (Netherlands Amateur Photographic Society) of Amsterdam, founded in 1887, is the oldest photographic society on the continent of Europe.

Dutch photographers are divided in their approach between the romantic and the modern as sponsored by such organizations as the Netherlands Fotografen Kunstkring or N.F.K. (Netherlands Society of Photographic Artists) and the Gebonden Kunsten Federatie or G.K.F. (Federation of Modern Craftsmen).

Publications. Holland produces a fair amount of photographic literature. Periodicals include the magazine *Focus*, established in 1914, and the younger *Foto*. Amateur cinematography is catered for by *Smalfilm*, while *De Fotohandel* and *Foto Mercuur* are directed at the photo-dealers. A large number of periodicals and books in English, German and French about photography are imported, since a very high proportion of Dutch photographers are able to read these languages. Books and articles by Dutch writers are also regularly translated into other languages. D.B.

HOLLYER, FREDERICK, 1837–1933. English portrait photographer and specialist in reproductions of paintings. Best known for his platinotype portraits of artists and authors taken in their own surroundings 1890–1914.

HOLMES, OLIVER WENDELL, 1809–94. American writer and amateur photographer. Collector of stereographs and designer of an open type stereoscope (1861).

HOME-MADE EQUIPMENT. Every photographer makes use of home-made accessories at some time or other, even if it is no more than a card clipped to the side of a lamp reflector to deflect part of the light.

TOOLS AND MATERIALS FOR MAKING EQUIPMENT

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Article	Used for	Type or Size	Remarks
Abrasives	Wood	Sand or glass paper	Available in grades of coarseness; use a cork sanding block for flat work
	Metal	Emery paper or cloth	Keep old and used pieces for final polishing. Available in various grades
Adhesives	Paper, cloth	Rubber gum	—
	Wood	Cold glue (various makes)	Follow simple directions on tin or tube, glue under pressure whenever possible
Bending bars	Bending sheet and strip metal	2 bars, 9 × ½ × ¼ in.	Make up from mild steel bar; fit a ¼ in. bolt and nut at each extreme end
Chisels	Wood	⅛, ⅜, ¾ in. suitable	Preserve original edge angle when sharpening. Use mallet and not hammer to drive
	Metal	¼ and ⅛ in. suitable	Cut along vice jaws or bending bars with a shearing action
Dies	Cutting screw thread on rods, bolts, etc.	13/16 in. diam. dies cut threads up to ¼ in.	Taper off end of work to be threaded. Cut with ½ turn forward and ¼ turn back
Files	Metal	6–8 in. medium double cut	Use with slow, steady strokes; relieve pressure on return stroke
Glass cutters	Cutting sheet glass	Diamond	Practice gives the "feel". Steady, confident strokes give cleanest cut. Support glass to be cut adequately along the whole length
		Wheel	Adequate for amateur requirements
Punches	Centring for drills	Centre punch	Place point at acute angle to locate spot, then tip to vertical to strike
	Setting pins and nails	Flat punch, nail punch	Hit squarely
Saws	Wood	Hand saws	Not recommended for small work
		Tenon	The best for small work
		Coping	For cutting round curves. Do not "force" cut
	Metal	Hack saws	Fine tooth blade for sheet and tube work (24 points per in.) Coarser (18) for heavier bar material
Soldering	Brass, copper, tin	Tinman's solder in sticks	Spirit or paste flux suitable. Tin pieces before "sweating" together over flame
	Electrical work	Resin-cored solder only	Hot iron, minimum of solder on joint
Taps	Threading holes	Taper, second or plug available in all sizes	Procedure as for dies. In blind holes, start with taper and "bottom" with plug tap
Vices	Wood	Various sizes	Steel frame type with renewable wood jaws preferred
	Metal		Make a pair of soft "clams" or false jaws, to hold finished work. Do not rivet on the jaw edges; the jaws are hardened and will chip

One of the main reasons for making a piece of equipment is that it will then exactly fill the particular need. Another equally important reason may be the cost of the manufactured article. This is especially so with elaborate and expensive items like enlargers. Here, the time spent on assembling, testing and adjusting is not something which the home builder has to charge against the cost. The manufacturer cannot help but pass this expense on to the purchaser.

Dependent on the equipment and ability of the builder, the home-produced article may or may not be as presentable or efficient as the factory-made tool. The finish is merely a matter of taste on the part of the builder. Relative efficiency is a thing which the user will have to consider when deciding whether to build or purchase. Many items of equipment are available in different standards of accuracy, and with the normal facilities of the home builder he cannot hope to produce an article comparable to the best commercial product.

This is the case with colour filters, to take one example. Many manufacturers offer a range of filters made from optical glass dyed in the mass, and worked to the same precision limits as apply to lenses. They are therefore expensive, and are used where the utmost scientific accuracy is necessary. However, where the requirements are not so exacting, a less accurate and much cheaper type may be perfectly satisfactory. Such an alternative range is often offered by the same manufacturer.

It is here that the home-made article begins to be a worthwhile proposition. Correctly coloured filter gelatin is available very cheaply, and it makes the production of a set of cemented glass filters in a range of colours a practical project. Gelatin filters can be made exactly to the user's requirements for size, shape and colour with next to no equipment. Even coloured plastic sheet has been used successfully.

Bellows. New or replacement bellows for enlargers, etc., can be made up quite well by most handymen. Some patience is required here in marking out, although this only entails simple geometry.

Materials required for first-class job are:

(1) Thin black leather "skiver", which can be obtained from any leather shop. This is not very expensive and is more supple than most other materials that have been used.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

(2) Some very thin material—such as that from which a good quality pocket handkerchief is made.

(3) For stiffening purposes ordinary drawing paper between the leather and material will help to keep the folds in the finished bellows.

(4) Rubber solution as an adhesive.

Quite good bellows can be made up from ordinary stout brown wrapping paper for those who cannot undertake the more elaborate job.

Unorthodox Materials. Home-made colour filters are only one example of how the home builder can profitably consider substitute materials. While camera bodies today are largely die-cast in light alloys, not long ago they were made of wood and wood is still an excellent stand-by for the photographic handyman. There is no reason to be shy of trying unorthodox or unconventional materials. In these days of plastics, resin-bonded plywood and super-strong cold-setting glues, he has available a host of easily-worked materials denied to the earlier worker in ordinary wood.

To take another example, commercially produced lens hoods are generally metal spinnings but an equally strong and in some ways superior hood is easily made from thin plywood. Most of the principal metal components of an enlarger can be made of wood, and have been so constructed in hundreds of successful cases.

Many commercial components—e.g., enlarger parts, tripod heads, rangefinder bodies and the like—are castings, often in light alloys, but it is nearly always possible for the metal worker to fabricate similar items from sheet and rod. Brass is generally a suitable material, as it is easily soldered, but, if there are no soldiered joints, aluminium is an easier metal to work.

Given only an elementary equipment of hacksaws and files, quite complicated items can be built up without any professional skill.

Apart from soldering (which is not everyones' forte) quite a large proportion of home-made metal equipment can be assembled with small brass screws and nuts. These are obtainable from any electrical or ironmonger's shop—sized from No. 1 B.A. to No. 6 B.A. would be found very useful. Many uses can also be found for aluminium or copper rivets.

Sheet metal work is something else which the home constructor needs no elaborate plant to tackle successfully. While the manufacturer uses bending and folding machines to make his shapes, the home worker can produce a satisfactory job by bending his sheet between two bars held in a vice and cutting out his shapes with hand snips. Enlarger bodies, dishes, reflectors, lenshoods and darkroom lamps are just a few of the sheet metal items which are readily produced by "one-off" hand methods.

Hand-shaping methods can be applied to many other simple things—e.g., plastic print tongs and pulleys, wooden masking frames, drying racks and metal dishes.

Adapting Scrap. Many home-made articles can be produced from scrap or discarded material. Many examples will spring to mind of scrap articles and materials which need little work to adapt them for photographic purposes: roller squeegees from rubber hose and a length of wooden broom handle; enlarger lamphouses from paint or other cans; reflectors from aluminium pudding basins; safelights from coloured glass jars—the list is endless. And there is no limit to the ingenuity which can be brought to bear in recognizing a photographic use for improbable material.

The great attraction in this pursuit lies in the fact that the final product often costs literally nothing. In some cases the appearance of the finished article may betray the original purpose of the material used, but if the user is satisfied with its performance that is all that matters.

Ideal Facilities. At the other end of the scale comes the amateur who can call on the resources of an enthusiast's workshop, containing machine tools and precision equipment. Many an amateur engineer and craftsman has built up such an outfit. Access to or the possession of a lathe opens the door to precision machining comparable with the best from any factory. The amateur's methods will be different, and his production will take longer, but his results will be in no way inferior to the factory-made article. Indeed, they may well be better and more adapted by individual needs.

The importance to photography of the home constructor has been well recognized in the number of books and magazines giving designs, instructions and hints on building. These provide valuable information and short cuts for making serviceable equipment with little or no skill or training. And there is nothing to be ashamed of in home-made equipment; after all, the prototype of every successful new device was once a "home-made" project.

Tools. While many articles can be made with the simplest tools such as are found in every household, the scope of the amateur can be greatly extended by adding a few others as included in the list above. Generally, the cost will be saved on the first few items made with their assistance. L.C.M.

HOMOLKA, BENNO, 1860–1925. Austrian chemist. Worked in Höchster Farbwerke, near Frankfurt, specializing in dyestuffs and photographic chemistry. In 1904 discovered pinacyanol, the red sensitizer, and pinacryptol green, the desensitizer. Also invented a dye-print process.

HOOKE, ROBERT, 1635–1703. English physcist and experimenter; assistant of Robert Boyle. Reported on a projection system in a light room 1668. Designed a conical portable camera obscura, 1680. Hooke made many contributions to microscopy.

HORGAN, STEPHEN H., 1854–1941. American photographer and writer on the photomechanical process. One of the pioneers of the use of half-tone blocks for newspaper printing, the first being published in the New York *Daily Graphic* in 1880.

HORIZON. Line where the earth and sky appear to meet. The position of the horizon in a landscape determines where the interest of the picture lies—if it is nearer the top of the picture than the bottom, the interest is in the landscape, and vice versa. That is why it should never run across the middle of the photograph, because that automatically splits the picture into two equal parts which compete for the observer's attention.

In a strong landscape such as occurs in hilly country, the horizon will be in the upper half, or, indeed, it may with advantage be eliminated by trimming away the sky. But in fen country, for example, or by the sea, a low horizon will carry a sky which dominates the scene with its cloud formation.

There are three different ways of adjusting the position of the horizon: by tilting the camera up or down; by keeping the camera level and raising or lowering the front; and by keeping the camera level and later leaving out part of the top or bottom of the negative during printing or enlarging.

Tilting the camera up or down introduces some distortion of the perspective of the picture. This passes unnoticed in a picture made up of rounded and irregular-shaped masses. But if there are any strong vertical lines—e.g., straight, tall trees, or the sides of high buildings—the tilt may be unpleasantly obvious. It is also impossible to join up the separate prints of a panorama series made with a tilted camera.

The ideal way of controlling the interest and adjusting the level of the horizon in the picture is to use a camera with a rising and falling front. This method does not distort any vertical lines in the picture and shows a natural perspective of trees and buildings.

If a landscape is photographed with a camera without a rising front, verticals will not be distorted so long as the camera is kept absolutely level. In this case the horizon will run across the centre of the negative, but there is no reason for it to run across the centre of the print. The top or bottom of a contact print can easily be trimmed away to give the picture the required balance, and in an enlargement the photographer is free to please himself about the position of the horizon. This is the only method open for making panoramas with a camera that has no rising front.

The camera viewpoint will determine how much is included in the foreground and how the foreground objects are laid out in the picture. Thus a low viewpoint will include only very near objects on a large scale, and these will hide anything farther away. If these subjects are taller than the height of the camera, they will also obscure the sky line and often exclude the sky altogether.

Conversely, a high viewpoint will not include any particularly near details, and provides an over-all view over medium distance objects, with the sky line formed by the limit of the field of vision. The higher the viewpoint, the farther this limit, and the less will appear of closer subjects.

The straight line of the horizon should generally be interrupted before it meets the edge of the picture. This is merely a matter of choosing a viewpoint that makes use of a suitable tree, or similar natural object. F.P.

See also: *Landscapes.*

HORIZONTAL ENLARGER. Earliest type of enlarger; an obvious extension of the old magic lantern, substituting a negative for the slide, and a piece of sensitized paper for the projection screen. This type of enlarger occupies more space than the modern vertical enlarger, but it is still widely used in making giant or mural enlargements.

HORSES. Successful photography of horses requires patience and a knowledge of horses. It is essential to understand how to show the points of different breeds correctly, both when stationary or in motion. It is useless to photograph a Thoroughbred in the same way as, say, a Shire horse or a Hackney.

Types. A light horse such as a Thoroughbred, Hunter or Hack must be photographed with the camera at a right angle to the subject to show its lines and lightness to full advantage.

The photograph may be taken from either side, although the near (left) side is the more conventional, but the horse must be posed with the foreleg nearest the camera slightly in front of the far foreleg, and the nearer hind leg a few inches behind the far hind leg. The tail must be shown in the normal position for the breed; in the case of an Arab it is carried almost like a plume. The head should be turned very slightly towards the camera with both ears pricked forwards and clearly visible. The neck should be flexed to show the crest (top of the neck)

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

HORSES FOR SHOW. Left: *Camera position (represented by shaded square) for photographing a race-horse to the best advantage.* Right: *Corresponding ideal position for a heavy horse, to show up strength and solid build.*

to advantage and there should be no suggestion that the horse pokes its nose forwards. The mane should be on the off (right) side of the neck and if shown should be plaited and not blowing about in the wind.

A heavy horse, such as a Shire or Clydesdale, may be photographed from a slight angle to show the powerful hind quarters to advantage. In this case the legs should be level, to convey the impression of strength and solidity.

The neck must be well bent to show its powerful line and high crest. There again the head should be turned slightly towards the camera so that intelligence in the eye and breadth of forehead may be shown.

A Hackney (trotting horse) should be photographed with the hind legs well back, so that the horse "covers a lot of ground" and conveys the impression of latent power.

When photographing groups of moorland or New Forest ponies, which cannot be posed, it pays to wait until two or three of the animals nearest the camera are in typical positions.

When a mare and foal are being photographed together the foal should stand very close to its dam on the side nearer the camera, with its face no farther forward than the mare's shoulder.

Equipment. The apparatus most favoured by animal photographers is of two kinds, either a reflex camera or a press type with a lens of slightly longer focal length than standard. A press camera should have a large direct vision viewfinder in which the subject can be watched easily for any sudden movement, such as the flick of an ear or a swish of the tail, either of which could spoil the result. A quiet shutter is important, because any sudden noise, however slight, is liable to cause a horse to turn its head or move an ear. The shutter must be capable of fast speeds in order to catch movement in jumping and other action shots.

Fast panchromatic material is used to give good colour rendering and to permit the use of fast shutter speeds. Filters are useful when photographing a bay horse with black points or when taking groups of ponies ranging in colour from chestnut to dark brown. A medium yellow filter is used when taking a grey horse, either jumping or whenever it is seen against the sky.

Lighting. The most suitable lighting for all types is given by rather hazy sunshine at about 45° to the subject, as such lighting will show the coat to advantage and the shape of the animal, without dark patches of shadow.

Horses Standing Still. Great care is necessary in choosing a suitable location to photograph a horse because it is most important that the animal should be standing on level ground and the background be as plain as possible. Precautions are taken to see that fences, stable doors or the branches of trees do not link up with the outline of the horse in any way. If the horse is to be shown unmounted, it should have either a headcollar or a bridle, with the reins resting on the withers. It should be held with a leading rein by a groom standing in front of the horse and well away from it. Where a horse and rider are shown, no one else is necessary to hold the horse, as the rider will control it and position it correctly. The camera is held so that it is at about the height of the horse's shoulder and must on no account be tilted up or the subject will be in very bad perspective.

It is usual for the animal to be in its summer coat and well groomed to bring out the sheen, which is a sign of good condition; the hooves should be oiled.

HORSES IN ACTION. Top: *The best time to photograph a jumping horse is at the take-off, or half-way across the hurdle. For the latter the jump must be clean; the take-off is nearly always reasonably safe.* Bottom: *A horse landing does not look elegant unless his back feet are well up, nor when he has touched down and is regaining his stride.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Horses in Motion. Jumping pictures, whether in the show ring or on the racecourse, are either taken with the camera placed very low down at an angle of 45° to the landing side of the jump, or from the side of the jump with the camera a little higher for a solid jump, such as a wall. The exposure must be made in the split second when the horse is over the middle of the jump.

Hackneys, when trotting, are photographed at right angles to the camera to show all four legs clearly and with the leading foreleg at the top of its action, as this "high stepping" appearance is the animal's most important characteristic.

Groups of riders—e.g., at a hunt—are taken from a three-quarter front view in order to show the faces of both the riders and their mounts.

Negatives should be very fully exposed to show all possible detail, and development time curtailed to produce a well graduated negative, full of detail. Over-development leads to a loss of quality in the rendering of the coat.

As this is a technical subject there must be no retouching or faking, the object being to portray the subject accurately but to the best advantage. R.R.

HORSLEY-HINTON, ALFRED, 1863–1908. English amateur landscape photographer, follower of P. H. Emerson's Naturalistic movement, and one of the leading spirits in the Linked Ring Brotherhood, founded by him in 1892. Horsley-Hinton was an influential authority on artistic photography and editor of *The Amateur Photographer* from 1893 until his death. He wrote a number of text-books, of which *Artistic Landscape Photography* is the most important.

HOT WATER BATH DEVELOPMENT. By using a bath of hot water it is possible to reduce the contrast of a print by as much as one paper grade.

In principle, the process is similar to water bath development of negatives.

After exposure in the usual way, the print is immersed in a standard developer until the image begins to appear. It is then transferred immediately to a dish of hot water at about 130–140°F. (55–60°C.), and allowed to develop out. If the image does not build up sufficient density, the print is returned to the developer for half a minute or so, and then returned to the hot water bath. This process may be repeated until the print is fully developed.

The decrease in contrast obtained depends on how much development the print received before transfer to the hot water. The sooner it is transferred, and the warmer the water, the softer the result will be. The temperature of the developer itself should be kept below about 60°F. (16°C.), so that the emulsion has a chance to become evenly charged with developer solution before any appreciable development takes place. If the emulsion is not uniformly saturated, the image may develop up unevenly in the water bath.

The water bath soon goes cold and becomes contaminated with developer, so it should be renewed every few minutes.

This method is not suitable for unhardened paper emulsions—e.g., as used for carbro and bromoil.

See also: *Contrast control; Water bath development.*

HOT WEATHER PROCESSING. Photography in the tropics demands a special technique of its own. But normal hot weather conditions (as experienced in fairly temperate climates) present no great difficulties except those concerning processing.

Normal processing temperatures range from about 60 to 75° F. (15–24° C.). If the processing solutions are warmer than 75° F. (24° C.) special precautions are then necessary. At these temperatures the gelatin emulsion takes up a lot of water and swells considerably. It becomes soft, highly sensitive to mechanical injury, and it may even melt and run off the support.

So in hot weather it is important to prevent the gelatin from swelling unduly, and to harden the emulsion layer to reduce the risk of damage from careless handling.

A change of one degree above, say, 75° F. has much more effect than a change of the same amount below 65° F., so accurate temperature control is even more important than usual—not only to keep the temperature of each bath constant, but to see that there is no variation between baths.

Swelling of Emulsion. To prevent the gelatin from swelling, the time that the film or plate stays in the various solutions—particularly before hardening—should be kept as short as possible. Low energy developers need very long development times and should be avoided, and a processing technique should be adopted that does not include any form of pre-soaking. The fixer solutions should be fresh to reduce fixing times, and washing should not exceed 30 minutes. At temperatures between 75° and 95° F. (24–35° C.) the washing process takes much less time, anyway.

Apart from these general precautions certain changes must be made in the developer.

All developers containing a high concentration of alkalis, such as sodium carbonate or hydroxide, soften the gelatin layer to some extent and are unsuitable for hot weather development. The most useful type of developer follows the metol-hydroquinone-borax formula.

Further, a neutral salt, such as sodium sulphate, reduces the absorption of water by the gelatin. So, although the salt generally increases

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the development time, add about 4 ounces (100 grams) of sodium sulphate crystals (Glauber's salt) to every 40 ounces (1,000 c.cm.) of working developer.

With a metol-hydroquinone-borax formula the development times are modified thus:

HOT WEATHER TIMES

Temperature of Developer °F.	°C.	Time of Development compared with time without Sulphate
75	24·0	As for 65° F. (18·5° C.)
80	26·5	As for 70° F. (21·0° C.)
85	29·5	Half time for 65° F. (18·5° C.)
90	32·5	Half time for 70° F. (21·0° C.)

Hardening the Emulsion. One—or both—of the following expedients will serve to harden the gelatin: an acid hardening fixer may be followed (after a brief rinse in an acid stop bath) by a special hardener. A suitable formula for a chrome alum hardener is:

Chrome alum	1¼ ounces	32 grams
Sodium sulphate, crystals	5 ounces	125 grams
Water to make	40 ounces	1,000 c.cm.

This hardener is effective as long as the solution looks bluish purple.

If the weather is very hot, with solution temperatures above 95° F. (35° C.) a formalin hardener may be used before development. This will tan the gelatin and prevent it from softening. After a good rinse the material is then developed in any tropical developer.

Technique. Apart from controlling the nature and temperature of the processing solutions, hot weather processing calls for some adjustment of technique.

It is most important to avoid handling the sensitized materials with hot sweaty fingers before processing. Unnecessary contact with the emulsion contaminates the surface and leaves fingermarks behind. Plates and films should be handled by the edges only. It is often difficult to observe this rule when threading a film into a spiral developing spool, and anyone who intends to do a lot of hot weather processing should buy one of the self-loading tanks or one of the daylight loading types.

Once the emulsion is wet, it is even more important to avoid touching it with the fingers. The ends of films developed by see-sawing should be held with stainless steel clips of the type used for hanging up films to dry. If the ends are held in the fingers the gelatin will melt and run.

In very hot weather it is as well to carry out all processing at the time of day when the temperature is lowest—i.e., in the early morning. At that time both the air temperature and the temperature of the water supply are generally low enough to permit processing without any special precautions. If the processing is being undertaken in a daylight developing film tank away from darkroom facilities it is a simple matter to load the tank during darkness the night before and carry out the processing next morning.

During hot weather there are more flies and dust about than usual. This means that the negatives must be dried off as quickly as possible in a current of filtered air—e.g., in a dry cupboard with ample ventilation holes at top and bottom, covered with muslin. L.A.M.

Books: *Camera in the Tropics*, by G. C. Dodwell; *Photography on expeditions*, by D. H. O. John (both London).

HÜBL, ARTHUR BARON VON, 1852–1932. Austrian officer. Studied chemistry; became director of the Militärgeographisches Institut (Military Geographical Institute), Vienna. Made valuable contributions to photogrammetry, especially as applied to map making, and to photomechanical processes, colour photography and colour printing. Published in 1882 a reliable process for the preparation of platinotype paper (invented by Willis). Worked on emulsions and sensitometry, invented multiple gum printing (1898), and improved the ozotype process (1903).

HUGHES, ALICE. Dates unknown. English photographer of royalty and society women from *c.* 1887 on, originally as studies for her father, a Court painter. Her fine platinotype prints are the epitome of an elegant age. Miss Hughes sold her London studio in 1910; opened up again *c.* 1916 and remained active until *c.* 1925. Autobiography: *My Father and I* (1923).

HUNGARY

Photography has deep roots in Hungary; in 1840, a year after Daguerre's invention was made public in Paris, the first daguerreotypes were displayed at the Magyar Tudomanyos Akádémia (Hungarian Academy of Sciences). Soon several daguerrotype studios were working in the capital of the country. The first of these studios was opened by Jakab Marastoni (1804–60) in June 1841. The calotype (talbotype) process did not come into general use in Hungary, but Archer's wet collodion process rapidly achieved popularity and soon more studios were opened in smaller towns. Many of the contemporary photographers were portrait painters who—though in most cases only temporarily—exchanged the brush for the camera. József Borsos (1821–83) was the most outstanding of these. Károly Szathmáry Pap (1813–87), painter and photographer, pioneered photographic journalism: as

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

early as 1854 he took pictures in the Crimean war.

In 1880 there were 257 independent photographers and 215 journeymen operating in Hungary, and Hungarian photographers were entering international shows, including the first world photographic exhibition held in New York.

In the last decades of the nineteenth century the development of photography as an art was greatly helped by the growing number of amateurs, some of whom proved to be photographers of outstanding artistic ability.

Hungarians also contributed to camera technique. Josef Petzval, the Hungarian professor, designed the first modern rapid portrait photographic lens. He was born in Szepesbela in 1807, became an eminent mathematician, and at the age of nineteen taught at the University of Pest. In 1840 he was invited to the University of Vienna, where he took charge of the mathematics department. Here he became interested in the optics of photography, and set out to design a system of lenses which would have a much greater speed than Daguerre's *f* 14 achromatic objective. He computed a successful four-piece asymmetric *f* 3·6 objective which was a revolutionary step forward, particularly in portrait photography where it reduced exposures to the order of a second or two instead of minutes.

Petzval's objectives were prepared and marketed by the Viennese optical firm of Voigtländer. His work gave a tremendous impetus to the science and art of photography by making the designing of lenses a matter for exact optical and mathematical computation. The Wiener Akademie der Wissenschaften (Vienna Academy of Science) and several other scientific associations made him an honorary member of their organizations and when he died in 1891 a street was named after him in Vienna. Today his name is known all over the world and in Hungary photographers revere his memory.

Ferenc Veress was the first person in Hungary to work on the problem of colour photography. His colour-sensitive emulsion was praised at the World's Fair in Paris in 1900 by A. Londe, head of the section on photography, and by Professors H. W. Vogel in Berlin and J. Eder in Vienna. Ferenc Veress tried out more than 500 colour emulsions, and colour contact prints made by him, preserved in the Magyar Nemzeti Múzeum (Hungarian National Múseum), have retained their bright colours to this day.

Photographic Industry. In Hungary a considerable photographic industry has developed since the end of the Second World War. The firm Forte established in Vac by the American Kodak company in 1923 made only photographic paper. It was damaged during the war, but since then it has been rebuilt, modernized, and made suitable for producing other photographic materials. This factory now makes photographic chemicals, photographic paper, plates and films and sensitized materials for industrial and medical radiography. The production of negative and reversal colour film started in 1963. The factory exports quantities of photographic materials, especially to the Eastern countries and to the tropics.

After 1945, the manufacture of cameras was started by a Hungarian optical works, beginning with the development of a roll film camera. In 1954, in addition to simple cameras, the mass production of roll film cameras of a more advanced type was launched. Optical instruments are also made.

Other Hungarian factories and precision engineering shops manufacture enlargers, laboratory materials and equipment, mainly for home consumption, and a number of chemical factories are engaged in turning out the basic materials for photographic chemicals.

The development of the Hungarian photographic industry is the result of continuing large-scale research work conducted since 1945, primarily in the laboratories of the various photographic manufacturers as well as in independent research laboratories. 1963 research led to the production of thin emulsions of high sensitivity.

Associations. The foremost organization of both professionals and amateurs is the Magyar Fotomüveszek Szövetsége (Association of Hungarian Photo Artists) in Budapest; a member of the Fédération Internationale de l'Art Photographie (FIAP). An organization of scientific experts called the Optical and Kinotechnical Association has made an immense contribution to the development of the Hungarian photographic industry. It maintains a large number of departments and research committees which embrace practically every branch of photochemical and optical science.

Hungarian photographic artists have a separate organization within the Magyar Képző- és Iparmüvészek Szövetsége (Association of Fine and Commercial Artists).

Photo-reporters working for the press are members of the photographic division of the organizations. Many press photographers are employed by the Magyar Távirati Iroda (Hungarian News Agency) which supplies photographs to all kinds of Hungarian and foreign publications. The most outstanding photographic artists and photo-reporters are engaged in training the younger generation of photographers. These experts hold lectures and arrange debates at which they analyse the artistic and technical problems of photography and criticize the pictures exhibited. The Hungarian daily papers and illustrated periodicals constantly publish the finest works of photographic artists and reporters.

The amateur movement in Hungarian photography is particularly strong. In a country of 10 million people the number of amateur

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

photographers is more than a quarter of a million and still increasing. Most amateur photographers today are members of photographic groups in their own place of employment and there is hardly a factory or institution without such groups. Amateur photographers in the provinces are usually members of groups organized in the cultural centres which are to be found in most villages and small towns, and the primary, secondary and vocational schools usually have photographic groups for pupils. There are about 2,000 such groups in Hungary.

There are twenty-eight amateur organizations throughout the country. The oldest of these is the Magyar Dolgozók Országos Müvészfényképezö Egyesülete (Hungarian Workers' Association of Artistic Photographers), recently renamed the Budapest Photo Club, with about 1,000 active members. This organization, formed in 1899, consists mostly of people who are not members of a factory, trade union or similar photo club.

Within the national organizations of amateur photographers, the factory photo clubs and the photographic circles of the provincial cultural centres, planned, artistic training is carried on. Annual national exhibitions of photography are held and several times a year local exhibitions are arranged, and there are lectures by experts and artists. Various organizations support the development of photographic art by sponsoring photographic contests. Amateurs also take part in international events.

Exhibitions. The first large-scale international photographic exhibition was arranged at Budapest in 1910, when about 2,000 pictures were submitted from all parts of the world. In the following decades exhibitions were held occasionally: international, national exhibitions, one-man shows etc. Since 1957 exhibitions have been regular and uninterrupted: five international exhibitions in Budapest and several salons displaying the art of a particular artist or groups of artists. On an exchange basis, works from many countries was exhibited in Budapest, collections of Hungarian works having been shown in Poland, France, The Soviet Union, German Democratic Republic, Czechoslovakia, etc. Most of the exhibitions were arranged by the Magyar Fotomüvészek Szövetsége (Association of Hungarian Photo Artists. The Magyar Ujságirók Szövetsége (Union of Hungarian Journalists) arranged two international Interpress exhibitions. The Magyar Távirati Iroda (Hungarian News Agency) used to exhibit the works of its photographers. Professional portraitists united in Fényszöv arranged in 1959 and in 1963 international exhibitions of portrait photography. Some of the exhibitions were organized around a particular theme for example, the Fifth International Exhibition "Women in the 20th Century".

Besides the exhibitions shown in the capital, several others are regularly arranged in country towns by the local clubs.

Art. Hungarians have contributed substantially to photographic art. From the period of daguerreotypes onwards, outstanding photographs have been preserved, showing the artistic value of masters like József Borses (1821–83), Károly Koller (1823–90), Antal Simonyi (1821–92) Sándor Strelisky (1851–1922) and Ede Ellinger. However, real striving after artistic expression began around the end of the century with the advent of amateurism. Thereafter many landscapes, city sights and genre pictures were taken. As in the West, from 1895 to 1925, pictorialism (imitation of paintings) was the main trend but already at that time there were some signs of photographic realism in Hungary.

The thirties brought the renaissance of Hungarian photographic art. Most characteristic of this period were the new themes: everyday happenings in the lives of simple people, typical figures of the masses, scenes with animals and landscapes. Some Hungarian photographers were fighting hard (for social progress.

Significant members of this group are: Kata Sugár (1910–43), Kata Kàlmán and Klára Langer. The latter has been awarded by the Hungarian Government the title of "Merited Artist". Several photographers have achieved world-wide success winning awards at many international exhibitions and competitions. Best known in this respect are: P. F. Angelo and Károly Gink.

Several gifted Hungarian photographers spent most of their life abroad, enriching with their works the culture of some western country: Làszlò Moholy-Nagy, Brassai (Gyula Halász), André Kertész, Robert Capa (Endre Friedmann) etc.

For the last thirty or forty years Hungarian photographers have been winning awards at international photographic exhibitions. Over a hundred gold medals and first prize certificates, won at the big international shows, testify to the high standards of their art. In 1939, 1,496 pictures were accepted from 100 Hungarian photographers, and were displayed at 70 international exhibitions. The 1940 *American Annual of Photography* carried a list of the world's best photographic artists and among the first ten were two Hungarian photographers. In our day, too, Hungarian workers are frequently awarded first prizes in international exhibitions. Aladar Szekely, Rudolf Balogh and Frigyes Haller and Ernö Vadas were outstanding photographic masters of the first half of this century.

Aladar Szekely (1870–1940), was a pioneer who strove to express the personality and character of his models. He discarded the artificial poses and the conventional studio scenery which created a false atmosphere and produced realistic portraits imbued with pro-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

found humanity. He published an album *Authors and Artists* followed by a volume of photos about the Hungarian poet Endre Ady.

Rudolf Balogh (1879–1944), a great figure in Hungarian artistic photography, established an entirely new style. He initiated themes based on the life of the Hungarian people, characteristic Hungarian landscapes, folk activities and ethnographic characteristics. His work won many international prizes. He died in 1944 at the age of 65.

Frigyes Haller (1902–54) scored many successes at international exhibitions with his bright village and peasant genre pictures and lively urban scenes. His greatest merit, however, lay in his work as a critic and teacher. He taught an entire generation of artistic photographers, and his pupils following in his footsteps are winning new honours at exhibitions at home and abroad. Haller was one of the finest and most highly cultured photographic aesthetes of his day and was for several years the President of the Budapest Photo Club.

Ernö Vadas (1899–1962) had a significant influence on Hungarian photography and was a master of themes showing everyday events in the lives of simple people; he also took landscapes and animals. After World War II, he began to apply new perspectives, mostly bird's eye views, to his work in cities, villages, factories, etc. He was the President of the Association of Hungarian Photo Artists.

In Press photography, Károly Escher and János Reismann achieved great success. Dr. Zoltán Tildy and Károly Koffán are noted for animal and bird photography while Dr. Ernö Vajda has become world-famous for his landscape and plant pictures.

Publications. In the nineteenth century, books on photography were published infrequently and they were mostly translations of foreign works.

Recently, however, a great number of books have appeared, some on the history of photography and others showing the latest developments in the form of Year Books.

Several magazines appeared at the beginning of the century, the first being *Az Amatör* (*The Amateur*). From 1921 onwards *Fotomüvészeti Hirek* (*Photo Art News*) gave technical and artistic advice to amateurs, while *Magyar Fotográfia* (*Hungarian Photography*) catered for professionals. *Fotoélet* (*Photo Life*) was launched in 1931. The current monthly for the amateur movement is *Foto* which, besides having articles on many aspects of photography, shows the best works of Hungarian and foreign artists. The Association of Hungarian Photo Artists publishes for its members a quarterly paper *Fényképmüvészti Tájékoztato* (*Review of Photo Art*) containing historical and aesthetical essays on photography.

Present Trends. In recent years, in addition to black-and-white photography, marked progress has been made in colour. The advent of colour materials of Hungarian manufacture and the introduction of special colour exhibitions has brought about a great increase in the popular interest in this field.

Present-day photographs by Hungarian artists are characterized by a feeling for reality, emotional depth, a healthy, optimistic view of life and simple technique. Hungarian photographic artists and amateurs draw the themes of their works from the everyday life of the ordinary people. They visit the workers in the factories, the peasants on co-operative farms, men of science in their laboratories and record their lives in the midst of their pursuits or out in the open on their days of rest.

They are interested first of all in the portrayal of reality, in the artistic presentation of life and not in the little tricks of photo-technique, the interplay of lights and shadows for their own sake, the tinsel of formal elements and artificial themes. To them, the main themes of photographic art are man and human creation. E.V. (I.H. & P.B.)

HUNT, ROBERT, 1807–87. English mineralogist. Outstanding research worker in the early days of photographic science. Writer of the earliest general treatise on photography and several important manuals. A founder-member of the (Royal) Photographic Society. Discovered (1844) that ferrous sulphate is a useful developing agent. Investigated the influence of the spectrum on light-sensitive substances (1843). Proposed several non-silver printing processes. Devised one of the earliest actinometers (1845).

HURLEY, FRANK, *c.* 1885–1962. Australian photographer and polar explorer. Official photographer to five Antarctic expeditions and in both World Wars. Best known for his pictorial record of Sir Ernest Shackleton's Antarctic expedition 1914–16.

HURTER, FERDINAND, 1844–98. Swiss chemist. Worked (from 1867) in an English chemical factory and was a colleague of V. C. Driffield. These two scientists and amateur photographers, not satisfied with empirical methods for measuring the speed of plates, established the first reliable approach to accurate sensitometry. His first work was to devise actinometers that would measure light intensity. Thereafter, in collaboration with Vero C. Driffield, worked out the method of measuring the sensitivity of photographic plates, involving the measurement of light intensities and the resultant densities. They also worked on the theory of the latent image, its development and the control of the development factor (gamma). Published a full description of the apparatus and methods in 1890.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The Royal Photographic Society granted Hurter and Driffield the Progress Medal in 1898 and instituted in 1918 the H. and D. Memorial Lectures. Collected works: *H. and D. Memorial Volume*, edited by W. B. Ferguson (London, 1920).

HUTTON, KURT (Kurt Hübschmann), 1893–1960. English photographer born in Strasbourg, (then) Germany. Opened a portrait studio in Berlin, 1923. 1929–34 worked as photographer to German illustrated weeklies, then settled in England, and became staff photographer to *Picture Post* from its foundation in 1938 until 1955.

HYALOTYPE. (Greek hyalo = glass). Name given by Frederick and William Langenheim of Philadelphia to their albumen-on-glass lantern slides in 1849. Hyalotypie was also the name given by F. A. W. Netto of Leipzig to the cliché-verre technique, 1840.

HYDRATE. Term applied at one time only to a salt formed by replacing one of the atoms in water by a metal.

Such a salt is nowadays called an hydroxide and the term hydrate is commonly reserved for compounds containing water—e.g., water of crystallization.

See also: *Chemicals; Crystal.*

HYDROCHLORIC ACID. Muriatic acid; spirits of salt; hydrogen chloride solution. Used in various bleaching baths.

Formula and molecular weight: HCl; 36·5.

Characteristics: Concentrated hydrochloric acid is a solution of about 32 per cent (by weight) hydrogen chloride gas in water. It is a colourless liquid with a strong pungent smell.

HYDROFLUORIC ACID. Hydrogen fluoride solution. Used in stripping solutions to remove gelatin emulsion layers from glass plates.

Formula and molecular weight: HF; 20.

Characteristics: Commercial hydrofluoric acid is a 50 per cent solution of hydrogen fluoride in water.

It is a colourless fuming liquid, and attacks glass. It is therefore kept in guttapercha, paraffin wax or polythene bottles. The solution is also very corrosive to the skin. The fumes must not be inhaled.

HYDROGEN PEROXIDE. Used in hypo eliminators.

Formula and molecular weight: H_2O_2; 34.

Characteristics: The commercial hydrogen peroxide is a solution in water, labelled in terms of volumes indicating how much oxygen gas it can give off. A 10-volume solution contains about 3 per cent pure hydrogen peroxide, a 20-volume solution about 6 per cent.

HYDROQUINONE. Hydrochinon; hydrochinone; quinol; 1 : 4-dihydroxybenzene. Used as a developing agent.

Formula and molecular weight: $C_6H_4(OH)_2$; 110.

Characteristics: White or pale buff coloured needle crystals.

Solubility: Slightly soluble in water at room temperature. Freely soluble in hot water.

HYDROXIDE. Chemical compound which contains one or more of the hydroxyl radicals; chemical formula, OH—e.g., sodium hydroxide (NaOH).

HYGROSCOPIC. Term indicating that a substance absorbs moisture from the atmosphere—e.g., common salt which becomes damp when exposed to the air.

HYPERFOCAL DISTANCE. When a lens is focused on infinity, the depth of field extends from infinity to a point nearer the camera. The distance from the camera to this near limit of the sharp field is called the hyperfocal distance.

If the lens is focused on the hyperfocal distance, the depth of field extends from half the hyperfocal distance to infinity.

See also: *Depth of field; Zone focusing.*

HYPERSENSITIZING. Term applied to any method of increasing the effective speed of an emulsion after manufacture and before exposure in the camera.

There are three ways of doing this: the film or plate may be immersed in a hypersensitizing solution; it may be exposed to the hypersensitizing action of certain vapours; or it may be hypersensitized by exposure to light. Some of these methods can also be used after exposure in the camera.

The Hypersensitizing Bath. Normally a silver bromide emulsion contains a certain amount of free potassium bromide. This reduces the sensitivity, but it is included to make the emulsion keep in store. A bath in distilled water removes most of the free bromide, and thus increases the effective emulsion speed, but of course films or plates treated in this way must be used as soon as possible after the treatment. This applies to all hypersensitization.

Bathing in an alkaline solution such as diluted ammonia (e.g., 1 part 0·880 ammonia, 8 parts pure alcohol, 24 parts water) is still better, and a 1 per cent solution of triethanolamine is equally effective.

There is an even greater increase in speed if the bath contains ammoniacal silver nitrate, say 1 per cent silver nitrate in distilled water with ammonia solution added until the precipitate formed at first is just redissolved. As this method increases the emulsion fog, the developer must contain a developer improver or anti-fogging agent.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

In every case the film or plate is immersed (in total darkness) in the solution, drained, and quickly dried in the dark. The speed increase is about 50 per cent (with plain water) to 200 per cent (with silver nitrate).

Exposure to Vapours. When the film or plate is hypersensitized by vapour, it is placed in a closed container with a little mercury or sulphurous acid solution. There is no need to unwrap the material, as long as the packing does not contain any metal. A closed box of plates or spool of paper-backed film can be hypersensitized in a sealed jar containing a few drops of mercury or potassium metabisulphite solution in a small dish. The mercury or sulphur dioxide vapour soon fills the jar, and penetrates the wrapping.

This treatment takes about 24 hours and although the vapour pressure (particularly of mercury) is very low at ordinary temperature, it is quite effective.

The results of vapour treatment are not very consistent; different materials require different periods of exposure to the vapour for the best effect. Some makes and types respond more readily than others. The speed increase varies from one make of sensitive material to another, and even sometimes with the same make.

Pre-exposure. Exposing the sensitized material very briefly to white light before exposure in the camera—i.e., flashing—increases the effective speed by giving the emulsion a threshold exposure, i.e., overcoming the inertia. Usually the fog is also increased.

The easiest way is to give the film a short initial exposure in the camera with the lens pointed at an evenly illuminated out-of-focus surface. The strength of the light and the aperture should be adjusted so that when the shutter is set to its fastest speed the exposure is about 1/200 to 1/100 that needed just to produce an image.

The extent of the increase in speed depends on the negative material used, and the most suitable level of illumination must be found by experiment. L.A.M.

See also: *Latensification.*
Book: *Developing*, by C. I. Jacobson (London.)

HYPERSTEREOSCOPY. Stereoscopic photography carried out with abnormal separation of the two viewpoints—i.e., from points more than the normal interpupillary distance (2½ ins.) apart.

If the viewpoints are separated by twice the interpupillary distance, the impression created by viewing the finished stereoscopic pair in a suitable viewer will be equivalent to looking at a half size scale model of the subject at half the actual distance from the camera to the original subject.

In other words, the subject will appear to be the same size as if it had been taken on a normal stereoscopic pair, but the stereoscopic effect will be doubled.

Terrestrial. Beyond a certain distance—about 200 feet—objects no longer produce a stereoscopic impression because the angle subtended by the observer's eyes is so small that both eyes see substantially the same picture. But if two photographs of the scene are taken from viewpoints sufficiently far apart (determined by the viewpoint distance), the resulting pictures will look stereoscopic.

In this way, distant mountain ranges can be made to stand out in relief by taking hyperstereoscopic photographs from two widely spaced camera positions.

Aerial. Consecutive photographs from an aerial survey series form hyperstereoscopic pairs because the respective viewpoints may be separated by a mile or more along the track of the aircraft. When such photographs are looked at in a stereoscopic viewer, the observer sees in effect a perfect scale model from a distance of a few feet.

This technique is employed in interpreting aerial reconnaissance photographs in wartime when it often shows up otherwise perfectly camouflaged buildings.

Astronomical. The same principle applies to astronomical photographs taken at consecutive instants of time. Because the earth is moving through space, the photographs are taken from viewpoints separated by a distance proportional to the time between one exposure and the next. Here again, seen in the viewer, the effect is that of a three-dimensional scale model. F.P.

HYPO. Every-day name for the fixing agent, sodium thiosulphate. Derived from the old and incorrect name, hyposulphite of soda. Nearly always used with an acid.

HYPO ELIMINATOR. Solution which removes small traces of hypo (sodium thiosulphate) from negatives and, more often, prints. By using a hypo eliminator, the washing time can be greatly curtailed—an advantage in high speed processing. A satisfactory formula is as follows:

Hydrogen peroxide (10 volumes)	5 ounces	125 c.cm.
Ammonia solution (0·880)	190 minims	10 c.cm.
Water to make	40 ounces	1,000 c.cm.

This formula converts any remaining traces of sodium thiosulphate into sodium sulphate, after which the hydrogen peroxide decomposes into water and the ammonia evaporates. There are no other solid compounds left in the paper as there are when potassium permanganate is used as a hypo eliminator.

The above solution is used after the prints have been washed for at least thirty minutes. The prints are immersed one by one, until the whole batch is in the solution. They must not be allowed to stick together, and should be turned over all the time. After ten minutes the prints are returned to the washing water for a further ten minutes, and then dried.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

If the prints are left in the hypo eliminator for more than ten minutes, it may slightly reduce the density of the lightest highlights.

1,000 c.cm. or 40 ounces of hypo eliminator are enough for about 120–150 6 × 9 cm. (2¼ × 3¼ ins.) prints or the equivalent in other sizes. The mixed solution does not keep, and is discarded after use. L.A.M.

HYPOSULPHITE OF SODA (HYPO). Incorrect but widely used name for sodium thiosulphate, the most common fixing agent for photographic sensitized materials. Discovered by Sir John Herschel, in 1819, as a solvent for silver salts, and recommended by him twenty years later as a photographic fixing agent.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

I

ICE RINK. Many colourful and spectacular ice rink productions are presented each year in addition to regular ice hockey matches, races, and normal skating events at the many ice rinks throughout the world. There are also touring ice shows that visit the theatres with suitable stage accommodation and facilities. All these spectacles are well worth photographing. Permission should, however, always be obtained.

Ice rink photography is considered the most difficult of all artificially lit stage subjects because of the size of the rinks and the area which can be covered by the skaters. The speed of the performers and the quick changes in the colour and power of the lighting all add to the difficulties of the photographer. Solo skaters move at high speed and rarely do their stunts in the same place twice, so it is almost impossible to keep them in focus.

A miniature camera is undoubtedly the most suitable for ice rink photography, especially because of the faster lenses available and the greater depth of field obtainable. Working at full aperture with fast film, sufficiently high shutter speeds can usually be chosen to freeze the movement of skaters, if not too close.

Electronic flash is widely used for publicity photographs at skating rinks. Such work is mostly done by official photographers and no attempt at using flash should be made without first obtaining permission. Most normal flash equipment is only powerful enough for closer shots of individual skaters, and for general views it is still necessary to resort to available light techniques. For stopping really fast action, however, electronic flash is essential.

The popular method of getting sharp pictures is to set the lens to cover a favourable zone, and concentrate on capturing interesting shots in that area. A preliminary visit helps in giving the photographer a chance to note where the pictures occur and select a suitable seat. The lighting is contrasty and a soft two-bath metol developer can be recommended for this and similar subjects. L.V.

I.C.I. STANDARDS. Alternative name for the C.I.E. standards of colour description. A system of reference for colours.

See also: *Colour measurement.*

IDENTITY PHOTOGRAPHS. The idea of using identity photographs on passports, shooting licences, etc., was first put forward in 1851 by Dodero, a Marseilles photographer. Identity photographs were first used in America by the Chicago & Milwaukee Railway Co. for season ticket holders in 1861.

Today photographic portraits are used for official records of identity on such documents as military identity cards, passes, and passports. Standard conditions are set out in detail in the British Standard Specifications (B.S. 967: 54) of which the main requirements are as follows:

All photographs must be taken full face with the head uncovered and with the camera not less than 4 feet from the subject. The head must occupy no less than half the print height.

Prints must be made on single weight paper with a surface that will take writing in ink. Prints for passports must in addition be on ordinary (non-waterproof) printing paper that can be mounted in the passport with adhesive.

Passport photographs must have a trimmed size of between $1\frac{1}{2} \times 2$ ins. and $2 \times 2\frac{1}{2}$ ins. and two copies are required.

For all other identity photographs the permissible trimmed sizes are 24×36 mm. and 38×38 mm. with a tolerance of plus or minus one millimetre on each dimension.

In the U.S.A. passport photographs have to be $2\frac{1}{2}$ ins. square, glossy, and two copies are required. Other identification pictures for licences issued by police departments (chauffeur's licence, etc.) are to be round, $1\frac{1}{2}$ ins. in diameter, two prints being required. Photographs for the armed services must be taken by the service issuing the identification card, and are $1\frac{1}{2} \times 1\frac{1}{2}$ ins. in size.

Colour prints are now also admissible as identity pictures in the U.S.A. if they satisfy the other conditions mentioned above.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

ILLUMINATION. In photography, illumination is the distribution of light from one or more sources over the subject being photographed and over the surface of the sensitive material. The illumination of the subject depends upon the type, power, position, and colour of the photographic lighting, and the illumination of the negative material depends upon all these, being modified by the size of the lens aperture and the scale of reproduction. But in each case the illumination obeys the same laws and is measured in the same units.

Intensity and Brightness. The intensity of a light can be measured in two ways—by measuring the actual energy present, or by comparing its brilliance with that of a standard light source.

To measure the energy of a light source it is made to shine on the blackened surface of a thermopile—a device which converts heat into electricity. The light is absorbed by the black surface and transformed into heat. The thermopile then transforms the heat into electricity and the electricity is measured with a suitable meter. This method is used for determining the efficiency of light sources—i.e., how much of the fuel consumed by the source goes into useless heat and how much into light.

The original standard of light was the flame of a specified type of candle burning at a specified rate and the illumination it produced at a distance of a foot is still known as a foot-candle of illumination.

The old standard candle gave a surprisingly uniform light, but in the course of time science has continued to change it for more accurate references. No matter what new reference is adopted, however, it is always quoted in terms of the brightness of the original candle.

The present standard source of light is taken as that given out by platinum at its temperature of solidification; and in order to preserve continuity with former standard candles it has been agreed that it should be regarded as having a surface brightness of so many "old" candles per unit area.

Luminous Flux. The light intensity is often also stated in terms of the luminous flux. The unit is the lumen, and is comparatively familiar to photographers who concern themselves with the efficiency of lamps. The lumen is the flux on a unit surface at a unit distance from a light source of one candle-power. If we imagine a sphere of unit radius surrounding the source, all the light flux falls uniformly on it, and each unit of area receives 1 lumen. As the surface area of the sphere is 4π units, a source of 1 candle power emits 4π, or about 12·6 lumens.

The Inverse Square Law. The inverse square law states that the illumination given by a light source varies inversely as the square of the distance from the source—i.e., the intensity depends on the area of the surface over which the flux is spread. This can be understood by seeing what happens when a cone of light falls on the same surface at different distances from the source. The total amount of light in the cone is always the same, no matter what the distance, but the cross sectional area of the cone at any point, and hence the area over which the light is spread, increases with the square of the distance from the source.

So the illumination in foot-candles at a distance D from a source of candle power C is equal to $C/(D \times D)$, i.e., C/D^2. If the light does not fall perpendicularly on the receiving plane then the intensity is reduced by a factor equal to the cosine of the angle between the incident beam and the normal or perpendicular to the plane.

The law is of fundamental importance in photography because it governs the change in exposure required when a light source is moved towards or away from the subject (or when the enlarger lamphouse is raised or lowered).

The law applies only to illumination by uniformly diverging rays from a point source—it does not apply to parallel rays which theoretically give the same illumination at any distance.

Brightness of a Light Source. Foot-candles are units of intensity of illumination and not of the brightness of a surface. The illumination of a surface is the luminous flux reaching it per unit area: the lumen per square foot was termed the foot-candle. The brightness or luminance of a surface depends on the amount of light falling on it and the proportion of this reflected, and is expressed by its luminous intensity per unit area (candles per square foot). The brightness has also been given by multiplying the illumination by the reflector factor, and expressing it in lumens per square foot (foot-lamberts).

Illumination of Image Plane. The aim of every means of illumination used in photography is to produce an image on the sensitive material in the camera. The degree of illumination of the image is governed by the brightness of the light falling on the object being photographed, the reflectivity of the object, and the relative aperture of the lens. If the brightness, B, of the object is measured in candles per square foot,

INVERSE SQUARE LAW. At 2 feet from the source a unit area receives only one-quarter the light it gets at 1 foot, as the same amount of light spreads over 4 times the area.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

then the illumination in the image plane, I, is given by the formula:

$$I = \frac{\pi B}{4f^2}$$

where f is the relative aperture of the lens.

If the emulsion had not been put in the camera but it had been put in contact with the object plane, the intensity of the illumination would be πB and then the ratio of the two intensities is $1 : 4f^2$. This ratio is of importance for finding the relation between the exposure necessary for printing by contact, and optical projection (enlargement). R.B.M.

Book: *Principles of Illumination*, by H. Cotton (London).

IMAGE. Rays of light reflected from an object and focused on a flat surface by a lens or mirror form patches of light on the surface corresponding to the bright parts of the subject. These patches of light together form a visible two-dimensional representation of the object. This recognizable picture of the object is called a real image.

The image may be formed on a plane in space, and not on a surface (e.g., in the plane of a clear screen in clear spot focusing). It is then called an aerial image.

When the eye looks at an object through a telescope, an optical viewfinder, or in a mirror, it sees an image of the object. This image cannot be focused and viewed on a screen, like a real image. This type of image is known as a virtual image.

In photography there is a third type of image—the invisible change in the emulsion produced when a real image is focused on it for the duration of the exposure. This image must be developed before it can be seen. It is called a latent image.

IMAGE AMPLIFIER. Electronic system for intensifying an optical image by conversion into electron streams followed by reconversion into light. In its simplest form it consists of an evacuated glass envelope with a semi-transparent photo-cathode at one end and a luminescent screen, similar to the viewing screen of a television receiver, at the other. The photo-cathode receives the primary optical image and reproduces it as a pattern of emitted electrons. These are accelerated away from the photo-cathode and focused on the luminescent screen by an electron lens (a suitably shaped electric field, or combination of electric and magnetic fields). The screen emits light under electron bombardment, and re-converts the electron image to a visible light image.

The Light Gain. The light amplification may be expressed as the photon gain, which is the ratio of the number of photons emitted by the screen to the number of photons incident on the photo-cathode. It depends on the quantum yield of

SIMPLE IMAGE AMPLIFIER. A, solenoid to produce focusing magnetic field. B, accelerating electrodes. C, photo-cathode. D, luminescent screen. E, photographic emulsion. The electron stream is shown dotted.

the photo-cathode for light of the spectral distribution of the primary image, on the accelerating voltage applied between the photo-cathode and the screen, and on the efficiency with which the screen converts the energy of the electrons to light.

The photon gain of simple image amplifiers may be as high as 100 for blue and ultra-violet light. Gains in red and infra-red are lower because of the lower quantum yield of available photo-cathodes. The resolution may be 50 line pairs per mm., comparable to that of fast photographic emulsions.

When the output of an amplifier is recorded photographically by using a lens to transfer the image from the screen to a photographic emulsion, the effective light gain is less than the photon gain, because the screen emits light in all forward directions, and the fastest lenses cannot accept more than about 25 per cent. This waste of light is avoided in some amplifiers which have the screen on the inside of a very thin mica window. The emulsion can be pressed into contact with the outside of the window, and substantially all the light output is used with little loss of definition. An alternative method is to use a fibre-optical window. This directly transmits the light from the screen to a photographic emulsion in contact with the window, with virtually no loss.

Amplifiers of this kind have been particularly successful in infra-red recording. Photographic emulsions are very insensitive at these wavelengths, and the conversion of the infra-red image to a visible image allows exposure times to be reduced by a factor of 1000 or more.

High-Sensitivity Systems. By using an electron lens which demagnifies the electron image, the light *per unit area* at the screen can be increased by a factor of 50 or more, over and above the photon gain. An amplifier of this kind, with a fast objective forming the input image, forms the basis of a camera of extremely high speed, and has enabled photography of starlit scenes with less than 1 second exposure. The same principle has been used in connection with the photography of faint X-ray fluoroscopic images.

The conversion of the optical image to an electron image also makes it possible to use image amplifiers as high speed shutters. The

CC-0. Panjab Digital Preservation Foundation, Chandigarh

passage of electrons between photo-cathode and screen is allowed or prevented at will by suitably altering the voltage applied to an electrode inside the amplifier. Exposure times as short as 10^{-9} second have been reached in this way.

Even if all the light output from a simple image amplifier is transferred to a photographic emulsion, the photons produced by a single photoelectron are far too few to produce a detectable image above fog. The higher photon gain needed to achieve this is obtained by incorporating stages of image-preserving electron multiplication between the photo-cathode and the screen. By this means amplifiers have been made with photon gains exceeding 10^5, and resolution of 30 line pairs per millimetre. They have been used in a variety of applications to photograph images which are so faint and transient that only a small number of photons is available. W.L.W.

LENTICULAR IMAGE DISSECTION: The lens images the event on to the lenticular plate. The aperture of a rotating perforated disc (Nipkow disc) is imaged on to the photographic plate by one of the lens elements of the lenticular plate. When the aperture of the rotating disc has moved to a new position (dotted) the event is imaged also in a new position on the plate. All other lens elements of the lenticular plate produce similar images. A, main lens. B, Nipkow disc. C, aperture in first position. D, aperture in second position. E, single element of lenticular plate H. F, image in first position. G, image in second position. J, photographic plate.

IMAGE DISSECTION. To take a series of exposures in one camera (as in cinematography) it is normally necessary to move either the film or the image by one picture width between exposures.

To do this rapidly requires both complicated and expensive equipment. However, if the image is divided into very many image points and these points separated by a number of point widths, then it is only necessary to move the image relative to the film by one point width to produce the next picture in the sequence. With one point width of, for example, one thousandth of the frame width, the required motion between frames has been reduced by this factor. If the separation between points is ten times the point width, then at least ten frames in sequence are possible and if points have this separation in both directions, then there can be up to 100 frames in a sequence.

With such an array of points, the simplest straight line motion is at an angle to the array and can, without overlap, readily give fifty frames.

The final record is a scrambled picture of all the different frames and requires un-scrambling before the frames can be seen separately. Fortunately it is possible to use the camera as its own un-scrambler.

PORTION OF A DISSECTED IMAGE. The image points are shown in the starting position. During a fifty-frame track the point A moves to the point B in its fiftieth position. All other points move simultaneously in the same manner.

These cameras can either be made of equal speed to other cameras at much lower cost or can give higher speeds than were possible by other cameras because of physical limitations. Variations in technique occur in the methods of dissection and image displacement.

Dissection. The pattern into which the image is to be dissected can be made as a grid having a small hole for each image point. The object can be imaged on to the grid and the transmitted dissected image then re-imaged on to a photographic plate or film. Assuming the holes to be arranged in a regular manner such that holes are ten hole widths apart, the total area of the holes to the total area of the grid will be 1:100. Thus only 1 per cent of the light will be available after the grid.

A more economical method in most cases is to make the grid of an assembly of very small lenses, each of which images the aperture of the objective lens on to the photographic emulsion as a small circle. Almost all the light reaching the small lenses is then transmitted. This system is more efficient while the *f*-number of the small lenses is better than that of the objective lens.

Such arrays of small lenses are available. In fact, film has been made with such arrays attached. It is more common to produce these as lenticular plates which consist of many semi-cylindrical lenses side by side. Two such plates, arranged with the cylindrical axes at right angles, are equivalent to an array of small lenses.

A single lenticular plate produces an image made up of narrow parallel lines. This can be used, but only permits deflection at right angles to these lines and the number of frames in sequence will be much reduced. Such a system

CC-0. Panini Digital Preservation Foundation, Chandigarh

is then very similar to a streak camera with multiple slits.

Deflection. The simplest technique uses a single lenticular plate (or array of parallel slits) and a simple mechanical movement of the photographic plate such as releasing it and allowing it to fall under gravity or driving it along with a spring or electro-magnet. The exposure must be limited to the time for the plate to move the distance between two image lines. Such a camera has produced ten frames at 100,000 f.p.s.

Using a similar dissection system and moving the image by a rotating mirror as in a streak camera, ten frames have been taken at 100,000,000 f.p.s.

With a crossed pair of lenticular plates, and a Nipkow disc fitted to the objective lens to produce a moving lens aperture, as many as 300 frames have been recorded in a single sequence at up to 100,000 f.p.s.

Image Tubes. Combining image dissection with all the advantages offered by the image tube gives the maximum possibilities. An image tube was specially designed having a metal layer with a suitable pattern of holes deposited on its photo-cathode so that additional optics were eliminated. This tube has recorded fifty frames in one microsecond that is, at 50,000,000 f.p.s. Given a suitable subject, it is capable of up to 1,000,000,000 f.p.s., and when the light intensification possibilities of such tubes are fully available, even higher speeds should be possible.

Fibre Optics. Long flexible bundles and face plates made of very fine glass fibres (diameters of less than 0·001 in. are possible) are opening up new optical techniques.

They could be readily applied as image dissectors with the added advantage that they can be used to re-arrange an image into a different pattern. Thus, in theory, one end of a fibre optics bundle could have the fibres tightly packed to accept almost all of an image, while at the other end the fibres could be arranged in one long single line of fibres. The length of such a line makes this impractical but with a number of parallel lines adequately spaced, the requirement for an image dissection camera is achieved. In the other systems, the image was, of necessity, only being sampled, but with fibre optics the chance of detail being missed is reduced almost to zero.

A camera with a fibre-optic dissector and a moving plate has produced twelve frames at 500,000 f.p.s. Image dissection techniques are also proposed to make high speed cine-radiography possible, a new tool of value to medicine.

Applications. Applications, to date, have been in studying rapid mechanical motions, projectiles and explosives for example. Image dissection cameras are ideally suited for applications in cine-microscopy and have been used in the study of liquids and particles such as coal dust.

Apart from high speed recording techniques image dissection is also suitable for storing a number of images on one film or plate—e.g. in document recording. The camera set-up is then quite simple—using a sampling grid with holes or a lenticular plate—since the only movement involved is the shift of the grid by one point or element interval from one exposure to the next. For reading, the multiple image is placed behind the same grid, and the latter gradually moved to assemble one image after another in turn.

IMBIBITION PROCESS. Any process for making prints by the selective absorption of dyes on a gelatin or similar surface.

See also: *Colour print processes; Dye transfer colour prints.*

IMPRESSIONISTIC PHOTOGRAPHY. In emulation of Impressionist paintings, some pictorial photographers in the early 1890s strove to achieve similar effects by blurring the image by optical means and printing or enlarging it on coarse paper. Soon, however, the Impressionists were no longer satisfied with these more or less legitimate means. The gum bichromate printing process introduced in

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

1894 by A. Rouillé Ladévèze. Problems of photographer to modify the image to such an extent that it could no longer be considered a reproduction of nature made by the camera. By adding different pigments and using rough drawing paper, the print could be given the appearance of a red chalk or charcoal drawing. By exposing the negative initially to coarse canvas the photograph could be made to imitate a reproduction of a painting. Thus Impressionism in photography dwindled into empty aestheticism.

See also: *Gum bichromate process.*

INCANDESCENT LAMP. Term generally applied to light sources in which the light is emitted by a glowing metal filament heated to incandescence by an electric current, in particular, tungsten filament lamps. Also sometimes applied to arc lamps and flash bulbs.

See also: *Filament lamp; Light sources.*

INCH (IN.). Lineal measure equal to 1/12 of a foot or 1/36 of a yard. In 1305 Edward I standardized the inch as equal to "three grains of barley, dry and round". Nowadays it is taken as the 36th part of the standard yard measure maintained at the Exchequer offices in London.

See also: *Weights and measures.*

INCIDENT LIGHT METER. Exposure meter which measures the intensity of the light falling on the subject (not that reflected from it).

See also: *Exposure meter.*

INDIA. Photography is not a part of the traditional Indian cultural heritage, having been introduced to India by a few European professionals. Amateurs were mainly influenced at first by British magazines, and later, by the flow of photographic literature from all parts of the globe.

History. Arab Pundits knew the basic optical principle underlying photography as early as A.D. 1038 and, according to references found in Amsu Bodhini Shastra, by Maharshi Bharadwaja, much of the art of photography, and its scientific principles, was known at the times of the Vedas thousands of years ago.

Although no direct part was taken by India in the invention of photography, Messrs. Bourne & Shepherd opened a studio in Calcutta in 1840—surely one of the earliest established in the world.

The early wet-plate process of photography was unknown in India, but after the invention of the dry-plate process European professionals introduced photography into the country.

The first pictorial photographer of outstanding merit in India was Shapur Bhedwar. He worked during the late nineteenth and early twentieth centuries, when modern electrical lighting not available and studios enlargers had to depend on daylight. Bhedwar was also the first Indian member of the London Salon, and several of his pictorial studies were exhibited in England, which was then the Mecca of Pictorial Photographers. J. S. Tarapore soon entered into a healthy rivalry with him, and this really opened the eyes of Indian camera-users to the possibilities of pictorial photography.

Industry. Until recently there was only one photographic factory, at Belgium, and its sole products were field-cameras in teak wood. This factory survived for some forty years until Japanese competition slowed down its progress. The import of small hand cameras for plates and film packs from Germany, and the growing demand for more handy equipment eventually stopped the manufacture of field cameras in India.

Up to the end of World War II, the demand for photographic goods in India was very small and many of the materials required could be imported easily and cheaply. In 1942 certain import restrictions were introduced, and after the war India began to become more photography-conscious. Both these factors boosted the demand for photographic goods and, after Indian Independence in 1947, some industrialists considered setting up factories in the country. A beginning was made with manufacturing photographic accessories such as albums, storage boxes, printing frames, leather cases and a few other small items.

In 1956, the import situation became serious when licences were cut down, but mid-1957 all imports of photographic equipment were banned. Only sensitive materials were allowed in to a limited extent. Even that quota was cut down from time to time and was, in 1963, practically nil. The supply of x-ray films is, of course, sufficient for medical purposes.

Today simple German cameras are made in Baroda under licence, and a few private companies have also started the manufacture of box cameras. A new large factory is nearing completion at Thana, Maharashtra State, some twenty miles from Bombay; this too is the joint venture of a German and an Indian organization, and will give India its first factory for manufacturing photographic papers. A Government factory at Ootacamund will, with French collaboration, manufacture roll films. Processing chemicals are also manufactured.

Although the prospects for the photographic industry in India are bright, certain high quality components are not produced in the country and this hampers the manufacture of lenses, shutters, and the like. The use of the full capacity of the factories is therefore dependent on availability of imports. Yet some photographic apparatus such as enlargers, slide-projectors, printing machines, trimmers, storing boxes for slides, flash bulbs, slide holders, masking frames, drymounting tissue

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

papers etc. is manufactured in a few larger cities.

Colour photography is practised on a limited scale in India. The reversal (transparency) process is favourite with the amateurs, and 35 mm. and 2¼ × 2¼ are the most popular sizes used. Very few do their own processing. There are well equipped processing laboratories in Bombay, Calcutta, Delhi, Madras, and a few other big cities. Colour printing is very scarce and there is much room for improvement.

Societies. About 1920 the Photographic Society of India was founded in Calcutta, but due to lack of enthusiasm its life was short. It was not until 1932 that a small band of very devoted and competent pictorial photographers formed themselves into an exclusive group called the Camera Pictorialists of Bombay. Their aims were the advancement of pictorial photography and its recognition in India as a branch of the fine arts.

The enthusiastic activities of this group resulted in a rapid growth of photographic clubs and societies, of which there are today about forty. It also pioneered the first all-India exhibition in 1933 followed by three international ventures in 1935, 1937 and 1939, where the cream of the world's pictorial workers exhibited.

In 1937, the Photographic Society of India was established in Bombay and is now the largest and most progressive photographic group in the country.

In 1953, some of the photoclubs joined together to form The Federation of Indian Photography, with its headquarters in Bangalore it is now affiliated to the F.I.A.P.

Another amalgamated group, formed in 1956, is the Indian Academy of Photography, with its headquarters in New Delhi. Dr. S. Radhakrishnan, President of the Republic of India, is the Patron of this Academy. It is the parent society of some of the best known and oldest societies in India. It is not affiliated to any foreign society.

In addition to the forty well-established photographic societies, transient clubs number up to one hundred. Some of these are affiliated to the R.P.S., P.S.A., F.I.P.P., or the I.A.P.

There are professional photographers' associations, each working on behalf of its own branch of the profession.

The Amateur Cine Society of India is the largest cine society in the country. It has held several successful film contests.

Exhibitions. The Simla Fine Art Society and the Bombay Art Society, which were founded in 1872 and 1888 respectively, laid the foundation for pictorial exhibitions in India by admitting pictorial camera studies to their annual art exhibitions, and contributed towards its promotion by offering attractive awards. In 1947, the Bombay Art Society, for the first time in its history, made H.E. The Governor of Bombay's Prize also available, in rotation, for photographic art at its annual exhibition.

Lord and Lady Canning opened the Exhibition of the Photographic Society on 2nd February 1856 in Bombay, perhaps the first photographic exhibition in the world, which opened on 22nd December 1852 at the rooms of the Society of Arts.

Publications. One of the main outlets for pictorial photography in India is the Press. For a long period *The Times of India's Illustrated Weekly* was the only paper in India that encouraged appreciation of pictorial sense. Later the *Kaiser-I-Hind*, a local Anglo-Gujarati weekly, and *Sakal*, a Marathi weekly, made a substantial contribution towards the advancement of photographic art. Purely photographic magazines have also played their part, and prominent among these were (but are no longer published) *Camera in the Tropics*, and *Indian Photography and Cinematography*.

There are now no regular publications on photography as such. Domestic ones solely devoted to photography, have never been able to compete with foreign periodicals entering the country. Enthusiasts, have from time to time brought out Indian annuals of photography. A few individual photographic societies also have their own monthly journals.

Training. As the need for the development of photography as a profession has become evident, courses in photographic techniques are now being held in many cities. Poona has a Government sponsored training centre, The Film Institute of India; students are eventually absorbed by India's large film industry.

Trends. The availability of modern miniature cameras, fast lenses and emulsions, have revolutionized photography in India to some extent. The new generation of amateurs tend to favour the candid type of work, rather than traditional pictorialism. There are, however, many amateurs who continue to follow the old school.

With the rapid industrial progress in India during the past ten years, photography has helped the engineer, the doctor and the technologist. Most of the large scale industries in India, such as, iron and steel, textiles, chemicals, and many others, as well as medicine, rely on photographic research in one form or another. Almost all of them have their laboratories, where photography plays a prominent part.

The film industry, which is one of the largest in the world, is fully equipped to meet the most modern demands. In recent years, photography has become the backbone of advertising and the Press, and plays an important part in business.

Photography plays a prominent part in visual education. Some of the advanced schools, colleges, and technical institutes have their individual photographic societies, and laboratories. Lectures and demonstrations are accompanied by projection of slides or cine-films. The U.S.S.R. Information Service, the British Information Service, and the United States

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

1894 by A. Rouille-Ladeveze enabled the photographer to modify the image to such an extent that it could no longer be considered a reproduction of nature made by the camera. By adding different pigments and using rough drawing paper, the print could be given the appearance of a red chalk or charcoal drawing. By exposing the negative initially to coarse canvas the photograph could be made to imitate a reproduction of a painting. Thus Impressionism in photography dwindled into empty aestheticism.

INCANDESCENT LAMP. Term generally applied to light sources in which the light is emitted by a glowing metal filament heated to incandescence by an electric current, in particular, tungsten filament lamps. Also sometimes applied to arc lamps and flash bulbs.

See also: *Filament lamp; Light sources.*

INCH (IN.). Lineal measure equal to 1/12 of a foot or 1/36 of a yard. In 1305 Edward I standardized the inch as equal to "three grains of barley, dry and round". Nowadays it is taken as the 36th part of the standard yard measure maintained at the Exchequer offices in London.

See also: *Weights and measures.*

INCIDENT LIGHT METER. Exposure meter which measures the intensity of the light falling on the subject (not that reflected from it).

See also: *Exposure meter.*

INDIA. Photography is not a part of the traditional Indian cultural heritage, having been introduced to India by a few European professionals. Amateurs were mainly influenced at first by British magazines, and later, by the flow of photographic literature from all parts of the globe.

History. Arab Pundits knew the basic optical principle underlying photography as early as A.D. 1038 and, according to references found in Amsu Bodhini Shastra, by Maharshi Bharadwaja, much of the art of photography, and its scientific principles, was known at the times of the Vedas thousands of years ago.

Although no direct part was taken by India in the invention of photography, Messrs. Bourne & Shepherd opened a studio in Calcutta in 1840—surely one of the earliest established in the world.

The early wet-plate process of photography was unknown in India, but after the invention of the dry-plate process European professionals introduced photography into the country.

The first pictorial photographer of outstanding merit in India was Shapur Bhedwar. He worked during the late nineteenth and early twentieth centuries, when modern electrical aids were not available and studios and enlargers had to depend on daylight. Bhedwar was also the first Indian member of the London Salon, and several of his pictorial studies were exhibited in England, which was then the Mecca of Pictorial Photographers. J. S. Tarapore soon entered into a healthy rivalry with him, and this really opened the eyes of Indian camera-users to the possibilities of pictorial photography.

Industry. Until recently there was only one photographic factory, at Belgium, and its sole products were field-cameras in teak wood. This factory survived for some forty years, until Japanese competition slowed down its progress. The import of small hand cameras for plates and film packs from Germany, and the growing demand for more handy equipment eventually stopped the manufacture of field cameras in India.

Up to the end of World War II, the demand for photographic goods in India was very small, and many of the materials required could be imported easily and cheaply. In 1942 certain import restrictions were introduced, and after the war India began to become more photography-conscious. Both these factors boosted the demand for photographic goods and, after Indian Independence in 1947, some industrialists considered setting up factories in the country. A beginning was made with manufacturing photographic accessories such as albums, storage boxes, printing frames, leather cases and a few other small items.

In 1956, the import situation became serious when licences were cut down, but mid-1957 all imports of photographic equipment were banned. Only sensitive materials were allowed in to a limited extent. Even that quota was cut down from time to time and was, in 1963, practically nil. The supply of x-ray films is, of course, sufficient for medical purposes.

Today simple German cameras are made in Baroda under licence, and a few private companies have also started the manufacture of box cameras. A new large factory is nearing completion at Thana, Maharashtra State, some twenty miles from Bombay; this too is the joint venture of a German and an Indian organization, and will give India its first factory for manufacturing photographic papers. A Government factory at Ootacamund will, with French collaboration, manufacture roll films. Processing chemicals are also manufactured.

Although the prospects for the photographic industry in India are bright, certain high quality components are not produced in the country and this hampers the manufacture of lenses, shutters, and the like. The use of the full capacity of the factories is therefore dependent on availability of imports. Yet some photographic apparatus such as enlargers, slide-projectors, printing machines, trimmers, storing boxes for slides, flash bulbs, slide holders, masking frames, drymounting tissue

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

papers etc. is manufactured in a few larger cities.

Colour photography is practised on a limited scale in India. The reversal (transparency) process is favourite with the amateurs, and 35 mm. and 2¼ × 2¼ are the most popular sizes used. Very few do their own processing. There are well equipped processing laboratories in Bombay, Calcutta, Delhi, Madras, and a few other big cities. Colour printing is very scarce and there is much room for improvement.

Societies. About 1920 the Photographic Society of India was founded in Calcutta, but due to lack of enthusiasm its life was short. It was not until 1932 that a small band of very devoted and competent pictorial photographers formed themselves into an exclusive group called the Camera Pictorialists of Bombay. Their aims were the advancement of pictorial photography and its recognition in India as a branch of the fine arts.

The enthusiastic activities of this group resulted in a rapid growth of photographic clubs and societies, of which there are today about forty. It also pioneered the first all-India exhibition in 1933 followed by three international ventures in 1935, 1937 and 1939, where the cream of the world's pictorial workers exhibited.

In 1937, the Photographic Society of India was established in Bombay and is now the largest and most progressive photographic group in the country.

In 1953, some of the photoclubs joined together to form The Federation of Indian Photography, with its headquarters in Bangalore it is now affiliated to the F.I.A.P.

Another amalgamated group, formed in 1956, is the Indian Academy of Photography, with its headquarters in New Delhi. Dr. S. Radhakrishnan, President of the Republic of India, is the Patron of this Academy. It is the parent society of some of the best known and oldest societies in India. It is not affiliated to any foreign society.

In addition to the forty well-established photographic societies, transient clubs number up to one hundred. Some of these are affiliated to the R.P.S., P.S.A., F.I.P.P., or the I.A.P.

There are professional photographers' associations, each working on behalf of its own branch of the profession.

The Amateur Cine Society of India is the largest cine society in the country. It has held several successful film contests.

Exhibitions. The Simla Fine Art Society and the Bombay Art Society, which were founded in 1872 and 1888 respectively, laid the foundation for pictorial exhibitions in India by admitting pictorial camera studies to their annual art exhibitions, and contributed towards its promotion by offering attractive awards. In 1947, the Bombay Art Society, for the first time in its history, made H.E. The Governor of Bombay's Prize also available, in rotation, for photographic art at its annual exhibition.

Lord and Lady Canning opened the Exhibition of the Photographic Society on 2nd February 1856 in Bombay, perhaps the first photographic exhibition in the world, which opened on 22nd December 1852 at the rooms of the Society of Arts.

Publications. One of the main outlets for pictorial photography in India is the Press. For a long period *The Times of India's Illustrated Weekly* was the only paper in India that encouraged appreciation of pictorial sense. Later the *Kaiser-I-Hind*, a local Anglo-Gujarati weekly, and *Sakal*, a Marathi weekly, made a substantial contribution towards the advancement of photographic art. Purely photographic magazines have also played their part, and prominent among these were (but are no longer published) *Camera in the Tropics*, and *Indian Photography and Cinematography*.

There are now no regular publications on photography as such. Domestic ones solely devoted to photography, have never been able to compete with foreign periodicals entering the country. Enthusiasts, have from time to time brought out Indian annuals of photography. A few individual photographic societies also have their own monthly journals.

Training. As the need for the development of photography as a profession has become evident, courses in photographic techniques are now being held in many cities. Poona has a Government sponsored training centre, The Film Institute of India; students are eventually absorbed by India's large film industry.

Trends. The availability of modern miniature cameras, fast lenses and emulsions, have revolutionized photography in India to some extent. The new generation of amateurs tend to favour the candid type of work, rather than traditional pictorialism. There are, however, many amateurs who continue to follow the old school.

With the rapid industrial progress in India during the past ten years, photography has helped the engineer, the doctor and the technologist. Most of the large scale industries in India, such as, iron and steel, textiles, chemicals, and many others, as well as medicine, rely on photographic research in one form or another. CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Information Service are helpful in spreading education and knowledge not only to students but also to the public in general. These services, and the Government's own cine-units, are giving valuable service in spreading knowledge to the thousands of villages of India and helping to remove illiteracy. J.N.U.

INDICATOR CHEMICAL. Substance which by a change of colour shows variations in the acidity or alkalinity of solutions, or detect the presence of silver or other compounds.

Three main types of chemical indicators are used in photography:

(1) pH (acidity) indicators,
(2) silver indicators, and
(3) hypo indicators.

Hypo indicators are generally used only in solution, pH indicators may be used in solution or in the form of test papers impregnated with the indicator, while silver indicators are generally used as test papers.

pH Indicators. These are organic dyes, usually weak acids or alkalis, which change colour at different degrees of acidity (i.e., at different pH values) of a solution.

The best-known pH indicator is litmus which is red in acid solutions of a pH below 5 and blue in alkaline solutions of a pH greater than 8. The point of change is therefore near the point of neutrality (pH 7).

Litmus is generally used in the form of litmus test papers for testing the acidity of stop baths and acid fixing baths. If the paper turns blue or even just mauve on insertion in the bath, the acidity is spent and the acid stop bath needs renewal. In the case of the fixing bath more acid has to be added, provided the fixing capacity is not exhausted as well.

Some indicators may be added in solution to provide a continuous check on the state of the bath. An example is bromcresol purple which is yellow below a pH of 5, and turns purple at a pH above 7. The change is slightly on the acid side which is an advantage since it provides a safety margin. Furthermore, the change in colour of a stop bath containing this indicator is easy to see by the yellow or orange light of a darkroom lamp. Some commercially available stop baths do in fact contain such an indicator. Some indicators which change at the right pH are not visible by a darkroom safelight (e.g., yellow to red) and therefore not of practical use with stop baths.

Bromthymol blue, changing colour from yellow to blue between pH 6 and 8 is also suitable for this purpose. Most other indicator dyes change colour at a much lower or higher pH and are thus not much use with stop baths. They may, however, still be useful for checking the state of special processing solutions.

In practice most indicators are used in a 0·01 to 0·05 per cent solution in water or aqueous alcohol, and added to the solution to be tested at about ten drops per ounce.

Silver Indicators. These show the silver content of fixing baths, thus giving an idea of the state of exhaustion. Silver indicators are available in the form of indicator papers which are impregnated with a substance that precipitates the silver as a brown stain. The silver content of the bath is assessed by the time the test paper takes to discolour. Fixing baths containing more than 4 grams of silver per litre (35 grains per pint) for use with negatives or 1·5 grams per litre (14 grains per pint) for prints are no longer able to dissolve the unused silver compounds in the emulsion completely and must be discarded.

Hypo Indicators. These show whether washing is complete, or whether any hypo is left in the emulsion of the negative or print. The most common indicator for this purpose is a 0·1 per cent solution of potassium permanganate containing 0·1 per cent sodium carbonate. To test for hypo, drain the negatives or prints, and collect about ½ ounce (10–20 c.cm.) of the drainings in a test tube or glass measure. Add one drop of the permanganate solution; if the colour persists, the water is free from hypo. If the colour is discharged, make a blank test with washing water direct from the tap. Hypo is present if the colour is discharged more rapidly in the drainings than in the control water (more than one drop may have to be added). The blank test or control is necessary because the washing water may contain substances other than hypo which also decolourize potassium permanganate solution. L.A.M.

INDICATOR DYES

Indicator	*Acid State*		*Alkaline State*	
	Colour	*pH*	*Colour*	*pH*
Malachite green	Yellow Blue	0 11	Blue-green Colourless	2 13
Crystal violet	Green	0	Violet	2
Thymol blue	Red Yellow	1·2 8	Yellow Blue	2·8 9·6
Bromphenol blue	Yellow	3	Blue	4·6
Methyl orange	Red	3·1	Yellow	4·4
Bromcresol green	Yellow	3·8	Blue	5·5
Methyl red	Red	4·2	Yellow	6·3
Para-nitro-phenol	Colourless	5	Yellow	7
Litmus	Red	5	Blue	8
Bromcresol purple	Yellow	5·2	Purple	6·8
Bromthymol blue	Yellow	6	Blue	7·6
Phenol red	Yellow	6·5	Red	9
Cresol red	Yellow	7·2	Red	8·8
Naphthol-phthalein	Red	7·3	Blue	8·7
Thymol blue	Yellow	8	Blue	9·6
Phenol-phthalein	Colourless	8·3	Red	10·5
Thymol-phthalein	Colourless	9·3	Blue	10·5

INDUCTION PERIOD. Internal time between the immersion of a negative in the developer and the appearance of the first sign of an image. Important in factorial development.

See also: *Developing negatives.*

INDUSTRIAL PHOTOGRAPHY. Any application of photography or photographic processes used in an industrial organization. Such uses may be in research and development, for improving production efficiency, or in promoting sales and service, as well as the photography of industrial installations themselves.

Every facet of photography is used in industry: as an illustrative medium for advertising and publicity; as a medium of communication; to arrest motion or integrate the effect of long periods of time; to provide changes of scale; to observe, record and measure in places where human beings would be limited by danger, fatigue, climate or toxic substances; and to duplicate photographic records for wide distribution. Cinematography is used as a time microscope with a magnification of 800 times or more or to reduce time to an infinite extent.

Applications include:

(a) The entirely functional: e.g., non-destructive testing of components by radiography; scientific analysis by high-speed cine film; time and motion study by time lapse photography; reproduction of engineering drawings and commercial documents; communication of information by photo-drawings; measurement of dimensions by photogrammetry; the duplication of written and illustrated matter by photolithography.

(b) The illustrative and communicative: e.g., in sales literature, safety propaganda, technical reports and for customer information.

(c) As a recording medium; e.g., in electron-microscopy, micro-recording, and oscilloscope trace photography.

The industrial photographer should therefore have a wide range of basic skills plus special training in his particular industry. His knowledge should cover all processes from cinematography, sound recording and photolithography to colour processing, photomicrography, and photographic instrumentation.

Many industrial organizations employ staff photographers. Some have a centralized photographic and reproduction service while others have a number of units each responsible to a particular department. These units may be small or large, specialized or general.

The advantages to a company using an internal photographic service are: That the photographer can be called upon at short notice, and is familiar with the company's products. Such a unit is not subject to divided loyalty, introduces no security risk, can be tailor-made to the company's requirements; may be more economical than an external service; provides quick delivery; and retains possession of negatives without extra charge. Industrial organizations with or without staff photographers may use the services of free-lance photographers and outside studios. Such services are available for illustrative photography of high impact value and pictorial appeal, for technical and scientific applications and for document recording and reproduction. R.F.

INDUSTRIAL RADIOGRAPHY. Röntgen discovered X-rays in 1895, and in the same year he used his discovery to make an X-ray picture of the scale weights in a wooden box. This was the first industrial radiograph. Since that date X-rays have become an indispensable tool in a great many branches of industry—quite apart from their important uses in medicine and scientific research.

Non-destructive Testing. The principal use of radiography in industry is for non-destructive testing—i.e., examining castings, welds, and finished components for internal flaws without breaking them open or destroying them.

A weld or a casting may conceal a defect which will pass the usual physical tests and inspection, but cause the part to fail after some use. Previously such flaws could not be detected without destroying the part. This meant that no matter how many samples were taken, or what proportion of the finished articles were tested to destruction, the soundness of the part put into actual use had to be taken on trust. The risk was considerable in the case of highly stressed objects like flywheels, turbine shafts and aeroplane parts.

Radiography now makes it possible to check the internal soundness of anything from a weld or a light alloy casting to heavy iron

INDUSTRIAL RADIOGRAPHIC METHODS. Top: *X-ray tube as the source.* Bottom: *Radioactive substance used as source of gamma rays. In both cases the film records a shadow of the flaw (voids, cracks) in castings, welds, etc.* R, *source,* O, *flaw.* S, *shadow of flaw.* F, *X-ray film in contact with casting being radiographed for examination.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

PIPE WELD RADIOGRAPHY. 1. and 2. Longitudinal welds, exposed from the inside and outside respectively. The film must be long enough to cover the section of the weld to be investigated. 3. and 4. Circumferential welds. 5. Circumferential weld exposed through both pipe walls, producing oval shadow on film. R, radioactive source. F, film, W, weld.

castings several feet through. X-ray inspection is an accepted routine test of the welding that now often takes the place of rivets in the construction of bridges, ships, boilers and pipes. It is also used to test the fitness of trainees for employment as welders.

Portable X-ray units are used in the building trade to show the position of the reinforcing bars in concrete structures when machinery or plumbing has to be installed after erection of the building. In this way the holes for the pipes or holding-down bolts can be drilled to miss the metal and so avoid weakening the structure.

Quality of X-rays. The energy of radiation applied in industrial radiography covers a very wide range from about 20 kilovolts to several million volts. The choice for the correct voltage depends on the atomic composition and thickness of the specimen to be radiographed. For instance, steel thicknesses of 1 in. and 6 ins. may be radiographed with X-rays generated at 200 and 1,0000 kV. respectively.

High-speed Radiography. Very powerful units have been developed for studying fast-moving events, such as explosions which are normally hidden in smoke and flame, projectiles in motion in the barrel of the gun or just leaving the muzzle in the region of the flash. The same units are used for investigating how dense fluids flow in pipes, and how metal cracks under a sudden blow. Exposures in this branch of radiography may be as short as one millionth of a second.

Assembly Inspection. X-rays are also used for checking the correct assembly and spacing of the parts in many manufactured products—particularly where a number of components are moulded into a plastic body and cannot be easily inspected.

Manufacturers also use permanent and continuous X-ray inspection to verify the contents of packaged products and to detect the presence of foreign bodies in foodstuffs.

Soft X-rays (Grenz Rays). The generation of soft X-rays (i.e. of long wavelength) has made it possible to widen the field of application.

Hard X-rays will only show tone differences in the developed image if there are correspondingly well-marked differences in thickness or opacity in the subject. Soft X-rays, however, will show up comparatively small differences and so can be used to examine and record the internal structure of such substances as leather, wood and even glass. The soft rays are also useful for examining living plants and other biological specimens.

Gamma Rays. Gamma rays have a shorter wavelength than X-rays and so are more penetrating. They are given off by radio-active substances. At one time radium and its gaseous decay product, radon, were the chief sources available, but nowadays atomic piles are being used to produce a number of suitable radio-active isotopes, such as Cobalt 60, Iridium 192, Caesium 137, and others.

Gamma radiography is carried out by placing a source at a distance on one side of the specimen and a sensitive film on the other. When two lengths of pipe are welded together, for example, a radiograph of the weld is obtained by sliding a source along the inside of the tube until it lies at the centre of the weld. A sensitive film is wrapped around the tube at the weld and left for the required exposure time. The duration of the exposure may range from minutes to several hours, depending on the thickness of the metal, the diameter of the pipe, and the activity of the source. When the film is unwrapped and developed, it shows a radiograph of the weld in a straight line.

The radio-active source may consist of a cylindrical isotope only 2 or 3 mm. in height and diameter and is usually kept in a lead container. Sources of this size can be introduced into places that would be completely out of reach of the normal X-ray tube—e.g., inside pipes and drilled holes, to examine welds, cracks, and shrinkage. Because the source is relatively small, it produces well-defined radiographs.

Gamma radiography with isotopes is flexible, easy to carry out, and very cheap when compared with the initial and operating costs of an X-ray unit doing the same class of work.

Stereo-Radiography. The localization of defects can be achieved by stereographic methods. This may be done by calculating the depth of the defect within a specimen from measurements taken on a film on which two radiographic exposures were made in succession, each with the X-ray tube in a different position with respect to the specimen.

Assessment of Radiographic Quality. The technical quality of a radiograph depends on contrast and definition. The ability with which an industrial radiograph provides information concern-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

ing the internal conditions of a metal specimen can be assessed semi-quantitatively by measuring the sensitivity of fault detection. This is defined as the percentage sensitivity = d/t × 100 where d is the smallest detectable thickness and t is the total thickness of the specimen. Thus the lower the percentage value the higher is the sensitivity. The device used for this semi-quantitative assessment is a penetrameter. It may consist of a thin step wedge of the same material as the specimen being examined, or it may consist of a sheet of metal of a given thickness having notches of various depths. Also wires of different diameters embedded in plastic or rubber may be used. The percentage sensitivity is determined by establishing the smallest thickness of material which can easily be revealed by the radiograph. With X-and gamma rays a sensitivity of ½–2 per cent is attainable, depending on the material and thickness of the specimen and particularly on the quality of radiation applied.

Protection. Any person engaged in the field of industrial radiology has to take adequate protection against the hazards. In industry radiation protection is strictly controlled by statutory regulations made under the Factories Act in the United Kingdom. Similar regulations are in force in many other countries. The guiding principle for the operator is not to exceed a certain maximum permissible dose or quantity of radiation. He must be able to protect himself from the radiation behind a sufficient thickness of lead, bricks or other suitable material and by a safe distance from the source, and also to measure the dose he receives in a specified time. This is carried out by means of ionization dose rate meters and by wearing photographic dosimeters (film badges).

G.T.S. and R.H.H.

See also: *Dosimetry; Gamma radiography; High speed photography; Intensifying screen; Medical radiography; X-ray crystal analysis; X-ray film.*

Books: *Handbook of Industrial Radiography*, by J. A. Crowther (London); *A Further Handbook of Industrial Radiography*, by W. A. Wiltshire (London).

INERTIA. Particular value of exposure arrived at by continuing the straight line portion of the characteristic curve to meet the exposure axis. It is constant for any given combination of emulsion and developer and is the figure used in determining H. and D. speeds.

INERTIA. This is the point where the continuation of the straight line part of the curve cuts the fog level line, and is the basis for H. & D. speeds. It is, however, misleading, as a fast film 1 may have a higher inertia i_1 than a slow film 2.

When the speed of an emulsion is measured by the H. and D. system, the figure increases as the developing time is extended. At the same time the inertia falls to a lower value. The effect is due to the presence of free bromide in either the developer or the emulsion.

See also: *Speed of sensitized materials.*

INFECTIOUS DEVELOPMENT. Effect that can be observed in some negative images, particularly in process-type emulsions developed in a hydroquinone developer with a low concentration of sulphite. One of the oxidation products of the developer accelerates the action of the partly exhausted solution. The result is that lightly exposed parts of the image —e.g., the fringes of lines exposed by irradiation or halation—may develop to a visible image. This effect may cause blocking up in line negatives having fine close lines.

INFINITY (∞). Mathematical term for a dimension or quantity of sufficient size to be unaffected by finite variations. Also a position on the focusing scale of a camera lens. With the lens set to this position, the sensitized material is in its rear focal plane, and receives a sharp image of very distant objects.

Although only infinitely distant objects are perfectly sharp, all objects extending forward to the hyperfocal distance for the particular lens are rendered sufficiently sharp for most purposes. For checking the infinity setting of a lens visually on a focusing screen, the object at infinity may in practice be the horizon, or an object at 1,000 yards or so from the camera.

INFORMATION AND INQUIRIES. The answers to most technical questions about photography are usually to be found in books and in technical journals dealing with the special subject. Where the information is insufficient, authors, who can usually be approached through their publishers, will generally give the reader fuller details.

Non-technical information is sometimes more difficult to obtain, the chief difficulty being that the inquirer does not know where to turn and wastes time in trying the wrong source of information. For instance, manufacturers of cameras will not usually enter into correspondence with individual photographers, as they prefer them to deal with the retailer or agent. Chemical manufacturers cannot be expected to divulge the composition of proprietary solutions where the formulae have not been published, nor can this type of information be found elsewhere.

On the other hand, most information can be obtained from the editorial departments of

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

photographic magazines. Focal Press have a special Information Department, which will answer inquiries direct. A self-addressed, stamped envelope for a reply should always accompany the query.

The following list is intended to serve as a guide to those seeking information in Britain about some aspect of photography. Where more than one source of information is given, the most likely is listed first.

Books. Rare or out-of-print: Librarian, Royal Photographic Society of Great Britain. Current publications: photographic publishers, booksellers, photographic dealers. In Great Britain, any public library can obtain books available in other public libraries.

Advice on specific literature is also given by Focal Press.

Cameras and Accessories. Photographic dealers. Special books are published that deal with one make only—e.g., Focal Press *Camera Guide* and *Camera Way* series on individual camera techniques.

Clubs and Societies. Royal Photographic Society; Photographic Alliance of Great Britain; local public libraries; local newspapers; local photographic dealers.

Legal. General information: H.M. Stationery Office. Photographic: *The Market for Photographs*. Literary: *The Writers' and Artists' Year Book*.

Customs. Full information can be obtained from H.M. Customs and Excise. Leading photographic dealers are usually prepared to assist by answering queries on this subject.

Employment. Local branch of Ministry of Labour. Institute of British Photographers. Vacancies are often advertised in *The British Journal of Photography* and other photographic magazines.

Examinations. Examinations to test various grades of proficiency are held by the Institute of British Photographers and by the City and Guilds of London Institute, Department of Technology.

Fellowship and Associateship. Particulars as to qualifications are obtainable from the Secretary of the relevant society. Honorary titles are sometimes awarded in recognition of special services.

Photographic Technique. Books and magazines supply information of varying degrees of technicality. The Focal Press Information Department answers specific queries by post.

Models. Model agencies. *International Model* Year Book (London). Sometimes art schools can put inquirers in touch with models. Some photographic classes occasionally employ models. Classified advertisements in photographic magazines.

Manufacturers' Instructions. For new apparatus, dealers and agents. For second-hand apparatus, manufacturers' instructions are often not available. Many popular cameras are dealt with in Focal *Camera Guides* and *Camera Way* books.

Photographic Permits. Appropriate authority or public relations office. It should not be assumed that permission to photograph will necessarily be granted—e.g., at some forms of public entertainment copyright difficulties preclude the issuing of permits.

Training. Professional: schools and colleges. For time tables and fees, apply to Principals of Institutes in question. If in doubt whether photographic instruction is supplied in any particular district, inquire from the local Education Officer. Examinations: Institute of British Photographers; City and Guilds of London Institute, Department of Technology.

Amateurs: clubs and societies. Evening classes of educational bodies—e.g., London County Council (information from local Education Officer or public library).

Selling Pictures. Photographic and press agencies; magazines, publishers. Publications: *The Market for Photographs*; *The Writers' and Artists' Year Book*; *Willing's Press Guide*. B.M.

See also: *Books on photography; Literature on photography; Museums and collections; Print libraries.*

INFORMATION IN THE IMAGE. Photographic efficiency and image quality are of particular concern in those applications where it is necessary to record as much information as possible in the photographic image. Astronomy and aerial photography are fields where the best possible photographic performance is often essential. Stemming from these and other closely-related scientific fields, new techniques have evolved with which photographic performance may be measured. These techniques have the same basis as those used to evaluate electrical communication systems, namely the Fourier analysis of complex waveforms.

By Fourier analysis a waveform may be resolved into a series of elementary (sine and cosine) waves of varying amplitude and frequency. The effects on the waveform of a transmitting or receiving medium may then be expressed as a simple scale factor for each frequency component. The frequency response of an amplifier provides a familiar example of this, and temporal frequency in the electrical case is replaced by spatial frequency when discussing optical and photographic image quality.

The photographic layer consists of a more or less random distribution of grains in a less dense layer of gelatin, and there are two basic mechanisms which inhibit perfect photographic reproduction.

Firstly there is the scattering of light within the layer and chemical diffusion during development. These are included under the same heading since the effects of chemical diffusion are often indistinguishable from those of light scattering.

Secondly, superimposed on the developed image are those fluctuations in density which are due to the discrete granular structure.

Spread Function. A useful representation of

light scattering is provided by the spread function. This is the term given to the image density distribution which results from exposure to a pin-point of light.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The spread function is the basic unit of all image formation since any exposure can be considered as a two-dimensional array of point sources, each of which will give rise to an image density distribution which is determined by the spread function. The final image will be given by the summation of the spread functions, each having the same shape, but with size depending on the exposure intensity at that point and the density-exposure characteristics of the photographic layer. The imaging properties of a lens system or an aperture can also be represented by a spread function.

Although the spread function is such a fundamental concept, it has limitations due to difficulties of manipulation. For example, when a point of light is imaged by a lens onto a film, each element of the lens spread function will be further spread by the photographic layer. Prediction of the final image is then difficult, while the problem of deducing the exact form of the exposure from observation of the image is virtually impossible. It is to overcome these problems of image evaluation that Fourier analysis is necessary, and this leads to the concept of the transfer function.

Transfer Function. The transfer function may be obtained by analyzing the spread function into spatial frequency components. By definition it

SPREAD FUNCTIONS. 1. Original of a white line on a black background. 2. On plotting or intensity (I) against the distance (d) across the image formed by a lens this should yield a "square" curve. 3. In practice the image formed by the lens on a film tends to spread, giving this typical spread function curve. 4. The photographic process causes further spreading; here density D is plotted against distance (d) across the image. 5. The final density output, with superimposed noise due to granularity is even more distorted.

TYPES OF SPREAD FUNCTION. An original pattern of black and white lines can—according to the characteristics of the image recording system—yield either a squarish spread function (left) or a more pointed type (right). The squarish function yields greater visual sharpness (acutance); the second type of image spread is capable of greater resolution but decreased apparent sharpness.

may also be obtained by measuring the amplitudes of the images of sinusoidal patterns. For these images the sinusoidal shape is maintained, and the amplitude at any frequency is merely changed by a scale factor which is the value of the transfer function at that frequency. It is this property of the transfer function which makes it such a useful concept. For example, the overall transfer function of a camera system is merely the product of the transfer functions of the lens and the film.

The transfer function, also known as the contrast transfer function, is a two-dimensional graph. It is a plot of spatial frequency against contrast. Its shape shows how efficiently a lens (or film) system reproduces an image.

Granularity. Fourier analysis also proves useful for the description of photographic granularity. If a uniformly exposed and developed film is scanned with a densitometer which has a long, narrow aperture, then a one-dimensional density waveform will result which represents the distribution of the developed grains.

Granularity is very much a statistical property, and one useful method of statistical analysis is provided by the *autocorrelation function.* This measures the degree of correlation between the granularity fluctuation at any point of an image with those at every other point of the image. Although it provides a complete and fundamental description of granularity, like the spread function it is not always convenient when evaluating photographic image quality, and the *noise power spectrum* has distinct advantages.

The noise power spectrum results when the granularity waveform is resolved into spatial frequency components. It bears the same relationship to the autocorrelation function as the transfer function does to the spread function, and it may therefore be obtained by Fourier analysis of the autocorrelation function. It may also be obtained directly from the granularity waveform by a "power spectrum" analysis. The term "power" originates from the field of electrical communications and signifies that the mean-square fluctuation is measured rather than the mean fluctuation, since the latter is neces-

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

OPTICAL TRANSFER FUNCTION. This plot of image contrast against resolved spacial frequency shows how well a lens (or lens and photographic) system performs. The dotted lines indicate the response of a perfect lens at different apertures, limited only by diffraction. The solid curves show typical practical responses. The higher the OTF value at any point the greater the information recording capacity.

sarily zero. In electrical applications the mean-square fluctuation of a current or voltage waveform corresponds to electrical power.

Quantum Efficiency. There is a further interesting way of measuring the size of the granularity fluctuations. These fluctuations can never be less than the limit imposed by the fluctuations in the exposure which are due to the quantum nature of light. The ratio of these quantum fluctuations to those due to granularity is used to measure how closely granularity approaches its lowest value. This ratio is sometimes termed the *equivalent quantum efficiency*.

Different films may have widely differing combinations of transfer function and noise power spectrum, and so will have a wide range of imaging characteristics. This may cause confusion when selecting a film for normal visual purposes such as portrait photography. But for scientific purposes the choice is relatively straightforward, since the scientists' criterion is usually that the photographic image should have the highest possible signal-to-noise ratio. The signal size is determined by the transfer function and the noise by the noise power spectrum.

Information Theory. It is this consideration of signal-to-noise ratio which leads to the evaluation of photographic image by information theory. Information theory is the general name given to a series of theorems which define how much information can be obtained from a signal in the presence of a given signal-to-noise ratio. It happens that a measure can be given to "amount" of information which is intuitively satisfying and has scientific rigour. The unit of information is the binary digit or "bit", and corresponds to the amount of information which is conveyed by a "yes" or "no" answer when both were equally probable.

The *information capacity* defines the amount of information which may be stored in the photographic image. Calculations show that one square centimetre of film may be capable of storing more than a million bits of information. All these yes or no answers are about the intensity distribution of the exposure. The more questions that must be answered, the better the film that is needed.

Books: *Mathematical Foundations of Information Theory*, by A. I. Kinchin (New York); *The Theory of the Photographic Process*, by C. E. K. Mees (New York); *Fourier Methods in Optical Image Evaluation*, by E. H. Linfoot (London).

INFORMATION THEORY. General name given to theorems relating to the transmission and recording of information and which permit the evaluation of the efficiency of recording and reproducing systems, and the choice of systems for particular purposes.

The basis of these theorems is that "amount" of information can be given a precise scientific definition which is in keeping with intuitive ideas. The natural units of information fall on a binary scale, and the ability of a system to transmit or store information is sometimes termed the information capacity.

See also: *Information in the image.*

INFRACHROMATIC. Term sometimes used to describe emulsions sensitive to infra-red radiations, as used for infra-red photography.

INFRA-RED (I.R.). Band of invisible rays that occurs in the spectrum beyond the visible red region is known as the infra-red. These rays, which have a wavelength of roughly 7,000 to 150,000 Angstrom units penetrate fog, mist and haze more readily than visible light rays and the longer wavelengths transmit heat. Infra-red rays up to 12,000 Angstrom units will produce a developable image on specially sensitized photographic plates.

Long-wave infra-red rays also affect certain photo-resistor cells and can thus be used to see and record objects in visual darkness. Glass is opaque to infra-red radiation beyond certain wavelengths but rock-salt and some semi-conductor metals are infra-red transparent.

The sun's rays are rich in infra-red radiation, and any body heated to just below red heat will act as a source of artificial infra-red rays.

Flash bulbs are another convenient source of infra-red radiation. They can be screened with a filter which removes all the visible light rays and allows only the infra-red to be used for taking photographs.

Distant scenes normally obscured by mist or haze can often be photographed successfully by using a plate specially sensitized to infra-red rays and adding a filter over the lens to cut out all but the infra-red region of the spectrum.

INFRA-RED PHOTOGRAPHY

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

Infra-red photography is of interest to the amateur and commercial photographer and to scientists and technologists because it permits results to be obtained which are not possible with panchromatic films. In its practice there is scarcely any difference between infra-red and normal photography. The same cameras and light sources can be used, together with the common developers and fixing solutions. The main difference lies in the choice of film and the need for filters.

TECHNIQUE

The peculiarities of infra-red photography lie in the ability of the film to "see" what the eye cannot see (permitting, for instance, photography in the dark); in the fact that many materials reflect and transmit infra-red in a manner different from the way in which they behave towards visible light; in the ability of infra-red radiation to penetrate certain kinds of haze in the air so that photographs can be taken of distant objects which cannot be seen or photographed on normal films; and in the ability to photograph hot objects by the heat rays which they emit. These properties permit infra-red photography to be used as an important adjunct to photography by normal light.

The infra-red lies "below the red"—that is, it includes all radiations between wavelengths just beyond those of the deepest red end of the visible spectrum, and the invisible heat waves which can be felt but not seen. But though we are able to double our range of vision in the spectrum by using infra-red photography, there is a limit to the part of the infra-red which can be photographed.

Photographs by infra-red were made in the last century, but it was not until the early nineteen-thirties that it became possible to carry out infra-red photography with the ease and certainty of ordinary photography. Just as orthochromatic and panchromatic films owe their response to green and green-and-red light to the inclusion of certain dyes, infra-red-sensitive materials owe their response to special infra-red-dye sensitizers. The earlier infra-red-sensitive materials were quite low in speed, but with recent improvements in the methods of making photographic emulsions and the discovery of new dyes, it has been possible to make available for general use infra-red films which are at least as sensitive as the fast panchromatic films.

Infra-red photographs are indispensable to astronomers, physicists and other scientists and have permitted many important discoveries to be made. It was, in fact, with these discoveries in view that most of the development of infra-red films was originated, but out of this highly specialized development have come films of far broader interest. The visible spectrum ends to all practical purposes at a wavelength of 7,600 A., but films have been made, and are used by scientists, which respond to radiations beyond 12,000 A. Those which are used for general infra-red photography, however, must have good speed and in practice they respond to about 9,000 A. with a maximum response at a wavelength somewhat longer than 8,000 A.

Infra-red sensitive materials need special storage, and refrigeration is often advised. This is partly because the sensitizing dyes employed tend to be less stable, and partly because by their very nature infra-red emulsions are sensitive to heat radiations of the shorter wavelengths so that mere storage in darkness is not always sufficient.

Infra-red Sources. The light sources commonly used in photography are suitable for infra-red materials. Most of them depend for their visible light on heating certain materials to visible incandescence, but a great part of their radiation is nevertheless in the invisible infra-red region. The tungsten filament lamps of the normal and over-run (Photoflood) variety and the foil- or wire-filled flash lamps are especially suitable, since they have the peak of their emission in the part of the infra-red where the films have their maximum sensitivity. The natural incandescent light source is the sun. It is clear from its warming influence that it is a great source of infra-red, and, in fact, it is this rich source of radiations that makes outdoor infra-red photography possible.

In addition to the sources which depend on the heating of materials, there are some which depend on an electric discharge through gases in a tube. There are many such sources, but some, like the fluorescent tubes used for lighting, are not suitable for infra-red work. Electronic flash tubes are most satisfactory.

It is always necessary to use a filter for infra-red photography because all the normal films are highly sensitive to blue light and, if no filter were used, the infra-red effect would be largely masked by the blue exposure. The common yellow filters may be used, but it is best to use the standard red filters of the tri-colour type. More pronounced effects may be obtained by using deep red filters. Filters require an increase of exposure which is greater the deeper the filter.

Equipment. Normal cameras can be used for infra-red photography, but there are two points to be checked: the bellows, film holders and draw slides, although black, must be tested to ensure that they do not transmit infra-red; the focus of the lens in the infra-red may be different from that in the visible spectrum.

The camera and its attachments can be tested by loading film in the camera or in the film holder, searching it closely with a bright electric

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

lamp, and developing the film. Absence of fog indicates safety. The presence of fog means that the bellows (i.e., the camera) must be changed, or the film holder must be replaced by one that is opaque to infra-red. Some manufacturers test their holders for infra-red and guarantee them safe.

Most lenses do not have their best focus in the infra-red when they are focused for visible light. Usually it is necessary to rack the lens forward slightly, as if focusing on a nearer object. The exact distance to give a sharp image must be determined by a few tests.

For development, standard developers may be used. Fixing, washing and drying are as for normal photographic materials.

Lighting. Outdoor photography is done with the sun and skylight as the natural sources of infra-red, and a filter is used over the camera lens to confine the exposure to the longer wavelengths.

The normal rules for subject lighting are followed, although compensation must be made for the fact that the photographic contrast of scenes in the infra-red is higher than for ordinary photography.

In the studio with artificial lighting, normal tungsten filament lamps, photoflash-type lamps, Photoflood-type lamps, and electronic discharge tubes are all satisfactory. The lighting is generally flat from the front.

Filters must be used on the lens, or, to make pictures "in the dark", on the light source. Infra-red polarizing filters are manufactured for use over light sources and over the camera lens for special polarized-light photography in the infra-red. As in the case of all filters, those used over the lens must be chosen so that they will not impair the definition of the lens.

APPLICATIONS

For many years, the popular conception of infra-red photography was that it was a way of seeing through fog. This was largely the result of the sensational handling of the subject by the press. In fact, infra-red photography does not provide a way of seeing through fog, although it can improve visibility through certain kinds of haze.

Long-distance Photography. This property is particularly important for long-distance photography on the ground where the detail of distant objects is often obscured by haze, and for high altitude and especially oblique photography from the air. Actually, infra-red photography does not always result in a very marked increase in the range of vision, but it may increase the contrast of the distant subjects and thus the amount of detail which can be seen. This produces the effect of greater penetration.

For long-distance infra-red photography the modern fast infra-red film is used with a red filter equivalent to a tricolour red. By this means the "atmosphere" so dear to many landscape photographers is entirely lost, and the general effect is one of enhanced and distorted contrast. Grass and leaves of deciduous trees appear white as if covered with snow, although the coniferous trees generally appear dark. The clear sky is very dark, particularly away from the horizon and away from the sun. Clouds appear white and, in the case of heavy cumulus clouds, stand out strikingly against the dark sky. High, wispy clouds which may be invisible in an ordinary photograph may show up clearly. Water generally appears black, unless it is turbid with suspended matter.

Portraiture. Portraiture, outdoors or inside, is not satisfactory by infra-red unless for an occasional bizarre effect because by infra-red flesh has a chalky appearance, red lips are very pale, and eyes appear as dark spots. Sometimes, however, doctors have infra-red photographs made for diagnostic purposes. The infra-red tends to penetrate the turbid skin and show up the veins lying close to the surface, and from their appearance certain conclusions can be drawn.

Survey and Reconnaissance. In infra-red photography outdoors from the ground or from the air, grasses and the foliage of deciduous trees appear white because of the transparency of the green colouring matter, chlorophyll, in the infra-red, and the high reflectance of the cellulosic structure of the grass and leaves. The result is that the infra-red contrast of a landscape or an aerial terrain may be quite different from the visual contrast, and this, over and above enhanced penetration resulting from longer wavelength, may help to increase visibility of distant objects. Further, it helps in aerial survey and reconnaissance to distinguish deciduous trees and grass from coniferous, diseased and dead trees and burnt grass which tend to appear dark in an infra-red photograph.

In war, the infra-red is of potential use for camouflage detection, especially in areas where the day-by-day erection of camouflage cannot be observed. Most green paints, which match green foliage visually in the summer, are strong absorbers in the infra-red and appear dark in an infra-red picture, while natural green foliage photographs as white. Some paints have been developed in which the spectral reflectance is high in the infra-red and they are more difficult to detect by infra-red photography. Special multilayer colour films have even been made and used in which one layer responds to the infra-red and produces a distorted-colour picture in which infra-red-absorbing camouflage shows up as an abnormal colour.

In practice, infra-red photography has been used in forest survey to distinguish between stands of coniferous and deciduous trees, and it has even been stated that if a yellow instead of a red filter is used it is possible to differentiate between different types of conifers.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

An important application of infra-red aerial photography in war is its use for determining depth of water and detecting underwater obstacles off potential landing places on enemy coastlines. It has been claimed that by comparing infra-red and visible-light photographs in average coastal waters, depths to 20 feet can be determined to an accuracy of 10 per cent. It has been suggested also that the method might be applied to construction of charts, study of sandbars, silting of navigable channels, control of erosion and pollution, charting of currents and the study of marine life. Seaweed surveys have been made by infra-red photography.

In the Dark. Since the infra-red is invisible, photography in total darkness can be readily carried out if infra-red film is used and the light source is covered with an infra-red-transmitting filter.

Infra-red flash photography has been used in this way for many special purposes, such as press photography outdoors in the blackout during war and in other situations where a bright flash would be disturbing (or betray the photographer), detection of intruders and criminals in the dark, audience-reaction studies in lectures, training-film projection and motion-picture theatres, unobtrusive instrument recording in aircraft, dark adaptation studies of the eye, and photography of industrial operations which are carried out in the dark, as in the photographic industry.

Usually, filters which permit the passage of the minimum of visible light are used—and it must be recognized that deep red light can be very visible in the dark. The filters may be placed in holders over the reflectors, or the flash bulb or the jackets of electronic discharge tubes may be dipped in a dark, infra-red-transmitting lacquer. Normal safelight lamps provide a good lamphouse if an infra-red filter is used in the place of the safelight glass. Suitably dyed plastic bags have also been used as covers for flash bulbs.

In audience-reaction studies by flash, it is usually sufficient to cover flash lamps and reflectors with an infra-red filter, and point them to the ceiling as for bounce-flash to produce illumination which is invisible to the audience. (If a person looks directly at a flash lamp covered with a deep infra-red filter, he will be conscious of a red flash.)

A few deep ruby bulbs among the cove lights or in the exit signs of rooms can often provide enough unobtrusive illumination for short-exposure infra-red photography.

With the modern high-speed infra-red film, short exposures will give good photographs at the normal low level of illumination pertaining in motion picture theatres, night clubs, and so on. Under low levels of tungsten-filament lamp illumination, the fast infra-red film will permit fuller exposures than the fastest panchromatic films for the same exposure values.

Document Inspection. Infra-red photography has found several applications in criminological investigations and it is a standard tool in many laboratories for the study of faded, burnt, worn, dirty or altered documents; the differentiation between pigments, dyes and inks which may appear indistinguishable to the eye; examination and identification of cloth, fibres and hair; detection of secret writing, and a variety of other special applications.

In the study of documents, infra-red photography was dramatically used in the early thirties for showing up printing underlying the obliterating ink of censors which, although black to the eye, happened to be transparent to infra-red. In this respect, infra-red photography is an important adjunct to ultra-violet photography in document examination. Printed matter, engravings and photographs which have become indecipherable through dirt or age can frequently be revealed, mechanical or chemical erasure can often be determined even if overwritten, provided, of course, the overwriting is in an ink transparent to infra-red, and even writing originally on documents charred in fires has been made readable provided the charring has not gone too far. Infra-red photography has taken a place with chemical, ultra-violet and X-ray study in determining the authenticity of works of art.

Scientific and Industrial. Infra-red photography is one of the accepted tools of the applied photographer, and the imaginative worker should have little difficulty in recognizing its possibilities and enlarging its field. Among the special uses, mention can be made of: plant pathology, in the study of plant diseases where there is change in pigment or cellular material; palaeobotany, particularly in coal petrology; in the textile field for detection of irregularities in dyeing or weaving of cloth or damage to the fibres, particularly where the material is dyed a dark tone and visual examination is impossible; in photomicrography of deeply pigmented tissues and thick sections to show enhanced details of internal structure; in the study of furnaces while they are operating.

Since heated objects emit infra-red radiation, in some circumstances they may be photographed on infra-red films by their own rays. The surface temperature of hot objects such as hot plates, engine parts, stoves, cooling ingots and castings, has been studied in this way. The useful range is limited, however, because at temperatures below about 400° C. exposure times become impracticably long.

Infra-red photography is a tool of rapidly increasing importance in astronomy and spectrography. Through its means, hundreds of new lines have been recorded in the spectra of the elements, much has been learned of the composition of the stars and of the atmospheres of the planets, new stars have been discovered and the haze of nebulae has been penetrated to bring us a fuller knowledge of the universe. W.C.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

INFRA-RED SCANNING CAMERA. This uses a movable mirror to scan the subject, directing the infra-red rays on to a photo-electric detector. The output of this modulates the intensity of a glow tube, the light of which is focused on to the film by a mirror moving with the main scanning mirror. This reconstitutes a visible photographic image. A, camera back. B, glow tube. C, target scanning mirror. D, image scanning mirror. E, black body temperature reference. F, radiation beam from object. G, amplifier and electronic control system. H, mirror optical system. J, chopper to produce signal pulses. K, infra-red detector and pre-amplifier.

While direct infra-red photography is limited to a maximum wavelength of about 13,500 A, the recording of longer wave radiations is possible by certain other methods. For instance at very low temperatures the latent photographic image can be partially destroyed by long-wave radiations (the Herschel effect) of wavelengths extending beyond the 13,500 A limit. This is a somewhat indirect—and not yet practical—way of utilizing long-wave infra-red rays.

Thermography. While normal infra-red photographic techniques use radiation reflected from the subject to form images, thermography utilizes infra-red radiation naturally emitted by objects at all temperatures above absolute zero. Further, it works with infra-red receptors other than photographic emulsions, such as certain types of photo-electric and transistor cells. This extends the sensitivity range to wavelengths beyond 300,000 A and is suitable even for recording heat radiations from objects emitted at 0° C.

A thermographic recording camera consists of a moving mirror and mirror lens system which, between them, scan the subject being recorded, focusing the heat rays on to an infra-red detector. The scan moves over the subject area in a television-like pattern.

Radiation from successive small scanned areas is converted into an electrical signal which is amplified and used to modulate the light emission from a glow tube. An image scanning mirror, synchronized with the subject scanning mirror, directs the beam from the glow tube over a sheet of photographic material, reproducing the television-type scanning pattern. The intensities of infra-red radiation received by the detector from each subject point are thus reproduced by different exposures of various points of the photographic material during the scan.

The resulting thermo-photograph indicates a true spacial relationship of the radiation temperatures of the various details in the scanned areas. Tones ranging from black to white indicate increasing radiation temperatures. The actual temperature at every part of the image can be assessed from a grey scale recorded in the photograph, corresponding to calibrated radiation temperatures. This provides a possibility of analyzing the temperature of image portions in the picture with accuracy of a fraction of a degree C.

Applications of such thermographic scanning techniques include the analysis of military targets and backgrounds (the presence of vehicles on the ground can for instance be detected by the higher temperature of their engines), monitoring industrial process installations, testing heating and cooling systems, investigating the degree of heating-up of engines, electrical components and other machinery in use, as well as medical and biological investigations.

In the last case slight variations in the skin temperature of a subject may reveal hidden tumours and other clinical conditions.

INKS FOR PHOTOGRAPHS. It is necessary to choose a suitable ink for writing numbers or data on the emulsion of negatives or prints. Ordinary writing ink should not be used for reference numbers or data on the margins of negatives; there is a tendency for the ink to run; it is not easy to make it take on the smooth surface, and some inks tend to come off after drying.

The best ink for this purpose is black drawing ink which should be applied with a fine pen of the kind used for map drawing.

Ordinary commercial writing inks can be used for writing data on the back of prints. Most of these inks are permanent but if the print has not been thoroughly washed they may bleach, especially if the print is stored under damp conditions. Some of the inks used in ball point pens are not permanent, especially if exposed to strong light for long periods. A signature on the print should always be written in black drawing ink.

The choice of ink for titling prints mounted in albums depends upon the tone of the pages. On a dark toned page the white ink sold by photographic dealers for this purpose should be used. If the white looks a little too glaring it may be diluted with a trace of black ink. This

will give a grey tint which can be attractive on dark grey or black paper. For light toned or white pages black ink looks best.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

If required, a waterproof ink can be made up as follows:

Add ½ ounce of borax to 4 ounces of hot water and heat together with ½ ounce of shellac until most of it has dissolved. Pour off the clear liquid and mix with enough Indian ink or lamp-black to leave a good black impression.

Glossy surfaced papers and hardened negative emulsions are reluctant to accept inks and water-colours. The difficulty can be overcome by adding a drop of prepared ox gall (obtainable from any artists' supplier) to the medium, or by applying a smear of the preparation to the surface to be written or painted on. R.M.F.

INSECTS. It is assumed that anyone who is so interested in insects that he wants to make photographs of them will also know something of their habits; if not, it will pay him to find out. In this branch of photography few things help more than a knowledge of what the subject will do next.

Stalking insects in the field with, say, a reflex camera is good fun and it sometimes results in a good photograph. But in the open air it is difficult to keep the subject in one place, and there is usually a wind to make matters worse. It is also unlikely that the subject will be kind enough to pose against a suitable background. Far better results are obtained by bringing the insects indoors or, better still, by rearing them from the egg or caterpillar stage and taking their photographs by artificial light under controlled conditions.

Camera. The single lens reflex or a miniature with a close-up reflex attachment is the best camera for insect photography. The twin lens reflex and the conventional hand camera are unsatisfactory for such close-up work because they both suffer from parallax. As the aim is generally to get as large an image as possible on the negative, the camera must have a very long extension or be fitted with a supplementary lens to permit close-up work.

Lighting. For insects like butterflies, dragonflies and large caterpillars, two Photofloods will give all the light needed. They should be controlled by a series-parallel switch so that they can be run in series during the business of arranging and focusing the subject and then instantly switched to full brilliance just before making the exposure. Smaller insects are best illuminated by a focused spotlight, and restless subjects may have to be taken with a flash.

Some insects, in particular dragonflies, are quite docile in the dim light, but will fly as soon as the bright lights are switched on. Photographs of such subjects are best taken by focusing in as dim a light as possible and then making the exposure with a synchronized flash bulb.

Flash bulbs are also used to arrest slow movement like the crawling of a caterpillar. The flash bulb is held at about 4 feet from the subject for a lens aperture of *f* 26 and is kept well to one side to throw up the modelling of the subject in sharp relief.

High speed electronic flash lighting may be used to arrest the movement of insects that normally move about quickly and demand very short exposures and proportionately brilliant lighting. The duration of the flash is so short—anything down to 1/10,000 second—that movement ceases to be a problem.

Exposure. As in other branches of natural history photography, every detail must be critically sharp. This means small apertures and long exposures. It is impossible to give hard and fast rules about exposure, but a time of about one second at *f* 22 on a fast pan film or plate with two 275 watt Photofloods at 3 and 5 feet from the subject should give a reasonable negative.

Negative Material. The choice of negative material generally calls for a compromise between two opposing techniques: using a fast, but relatively grainy emulsion, and using a fine-grain, but relatively slow emulsion. If the image can be made large enough on the negative in the first place, then it is better to use a very fast panchromatic film or plate, since there will not be enough enlargement to show the grain.

But if it is impossible to get a big image on the plate to start with—either because the subject tends to move about, or because the camera cannot be focused close enough—then it is better to use a slower but finer grained emulsion that will stand the necessary extra amount of enlargement. A smaller image on the plate means that a shorter exposure can be given, and this helps to compensate for the slower speed of the negative material.

Colour. There is no special difficulty about photographing insects in colour. The technique is the same as that used for monochrome photography except that lighting, filters and exposures need even greater care than usual. It is even more difficult to give any guidance on exposures for colour than for black-and-white. The problem can be solved only by experiment, particularly as even individual makes of colour film vary from one batch to the next.

Large Insects. The larger insects are persuaded to take up a position on suitably arranged foliage set up in front of the camera. Butterflies are fairly docile in artificial light, and a patient operator can generally succeed in getting the subject to rest where he wants it by going to work slowly and gently. The members of some species will expand their wings in the light of the Photofloods; others—those that do not naturally rest with their wings open—may refuse, and have to be photographed with them folded.

With this type of subject there is a strong

CC-0. Agamnigatu Digital Preservation Foundation, Chandigarh

temptation to use a wide aperture and fast shutter speed to arrest movement. But the best photographs are made by the photographer who has the patience to wait until the insect is quite still and then to give a relatively long exposure. In this way the lens aperture can be kept small enough to give the necessary depth of field. If the insect is free to move, the image must be constantly examined through the focusing magnifier to keep it focused within the limits of critical sharpness.

Small Insects. The photography of small objects like eggs, young caterpillars and grubs of insects has to be handled by the special technique of low-power photomicrography. A magnification of about five times life size on the negative is generally sufficient. With larger magnifications than this it is difficult to obtain the necessary depth of field, even at very small apertures.

The enlarged image is best produced by using a short focus lens and a long camera extension. A camera with a normal extension may be mounted with its back to the lens panel of another with a long bellows. The subject of such large magnifications calls for a small spot of concentrated light.

Underwater Insects. Water-dwelling insects and pond life may be photographed either from above or from the side. When they are photographed from above, the insects are placed in a shallow glass dish with just enough water for them to swim in. This restricts their movement and keeps them within the limits of the depth of field of the lens.

When water insects are photographed from the side, they are confined in a very narrow Perspex or glass tank which leaves them freedom to move up and down, but not from front to back. This arrangement greatly simplifies focusing.

The field covered by the lens can be marked out on the side of the tank, so that once the lens is set to include the full width of the tank in its depth of field there is no further need to watch the image in the focusing screen. The photographer simply waits for the insect to move into the picture area, switches on the lights and makes the exposure.

This type of set-up leaves the photographer free to use a background of the most suitable tone to show up the subject and even to employ back lighting against a dark ground, perhaps the best type of illumination for dealing with the almost transparent hairs and antennae possessed by many water-dwelling insects.

When the subject is enclosed between glass walls in this way, the image on the focusing screen must always be examined very carefully for unwanted reflections with the full lighting switched on.

Life Cycles. Perhaps the most interesting insect photographs are those that show a series of events, like the successive stages in the pupation of a caterpillar, or a butterfly emerging from its chrysalis. This type of record calls for careful preparation because most metamorphoses of this sort are over very quickly. The camera, lighting and plate holders must all be ready for instant use, and the photographer must be prepared to keep up a continuous watch so as not to miss the start of the process.

Controlling Live Subjects. It is fairly common practice to control the movement of insects by stupefying them with carbon tetrachloride or ether, or chilling them in a refrigerator to slow down their rate of movement. This should be done only as a last resort with insects like silver fish and cockroaches that move at great speed and seek dark corners. In such cases the method of control should always be stated—e.g., etherized, temperature controlled, etc.

Photography in the Wild. In spite of the many difficulties inherent in attempts to photograph insects in the field, there are occasions when this is desirable.

When the insects are at rest, a tripod should be used; all preparations such as the setting up of the camera and the removal of unwanted foliage require great care in order not to disturb the insect. For the photography of insects feeding on flowers, and of other moving subjects, it is usually necessary to hold the camera in the hand, but sometimes a single support resting on the ground can be utilized to give extra steadiness. A compromise must be reached between a short enough exposure to arrest slight movement and a small enough aperture to give sufficient depth of field.

For this work, a single-lens reflex is desirable, and it is best to bring the subject into focus by moving the camera as a whole nearer to or farther away from the subject, rather than to use the normal focusing system of moving the lens in relation to the plate or film. If a reflex is not available, a rod may be attached to the camera so that this rod projects from the front, but is just out of the field of view. The camera, with its focus correctly set, is then moved bodily to or from the subject until the end of the rod is in line with the insect, whereupon the exposure is made.

When photographing moving insects with the camera held in the hand, it is as well to make several exposures of the same subject, as it is very probable that some will be spoilt by the movement of the insect or by camera shake.

Dead Insects. What has been said above refers to the photography of living insects. Photographs of dead insects should be made against a plain background. The subject should never, for example, be attached to a flower to make it appear to be alive. There are, unfortunately, in books on natural history, many such faked photographs, and in some of them the corpses are arranged in positions that the living insects would never assume in nature. Photographs like these bring discredit on natural history photographers and are greatly to be deprecated; if the insect is dead, it is better to be

honest about it and mount it like a museum specimen. No skill in disguising the withered shell of a dead insect can ever imitate the living reality. S.B.

See also: *Close-ups; Macrophotography.*
Books: *All About Photographing Insects*, by G. E. Hyde (London); *Entomological Photography in Practice*, by E. F. Linssen (London).

INSTANTANEOUS EXPOSURE. Old-fashioned term for an exposure made with an automatic shutter speed of 1/25 second or less. Nowadays it has no significance except that the initial "I" is still much used to indicate the automatic exposures on shutter controls.

INSTANT PHOTOGRAPHY. Photographic system that yields a finished picture immediately after the exposure—usually by processing within the camera.

See also: *Polaroid Land camera; While-you-Wait Photography.*

INSTANT RETURN MIRROR. Mirror system in single-lens reflex cameras where the mirror returns automatically into the viewing and focusing position immediately after the exposure. This may be coupled with an automatic diaphragm mechanism which at the same time re-opens the lens iris to its maximum aperture. Systems of this kind are usually built into cameras with focal plane shutters; they are rare with a diaphragm shutter.

See also: *Reflex camera.*

INSTITUTE OF AMATEUR CINEMATOGRAPHERS. Organization founded in 1932 to help amateur cinematographers by disseminating technical information and providing facilities for the exchange of views and experiences. All duties in the organization are performed in an honorary capacity.

The Institute has its headquarters in England, but its membership includes amateur cinematographers and a large number of societies and clubs in many parts of the world.

Membership is open to all *bona fide* amateurs who either practise or are interested in cinematography, and the council awards Fellowships to members in consideration of outstanding film productions or for services rendered to the movement.

Special publications, exclusive to members and affiliated societies, are issued at frequent intervals and the Institute provides technical advice, film and book libraries, and film and script criticism. Membership carries with it privileges for cheaper technical services and a low-fee lending library of outstanding amateur films. The annual film competition is the oldest of its kind in the world, and the prizewinning films are presented at the annual London Amateur Film Festival, sponsored by the Institute.

INSTITUTE OF INCORPORATED PHOTOGRAPHERS. Formerly the Institute of British Photographers. Was founded in 1901 to represent all who practise photography as a profession in any field and to establish for the profession a reputation commensurate with the importance of photography in the public service. It has played a major part in the development of professional photography in the United Kingdom during the last half-century. The Institute is frequently consulted by government departments and its recommendations contributed to the framing of the sections bearing on photographic matters in the Copyright Acts of 1911 and 1956.

The affairs of the Institute are regulated by its Memorandum and Articles of Association and the Companies Act, 1948. In 1960, the Institute was reconstituted as a professional institution with a new main object "To improve the technical knowledge and professional status of persons engaged in photography and ancillary occupations and to achieve uniformly high standards of professional conduct". The organization had previously been part trade association—a situation which was incompatible with the holding of professional examinations and the general development of photography as a profession.

The Institute is governed by a Council which is elected by the members and comprises twenty persons who are either Fellows, Honorary Fellows, or Associates. A number of standing or ad-hoc Committees are in operation, advising the Council on matters including the following spheres: advertising photography, cine photography, education, finance, industrial photography, medical photography, membership, professional fees, Photographic Convention, Register of Incorporated Photographers, qualifications, press photography and general practice.

Over one hundred meetings are held annually in many parts of the United Kingdom under the auspices of the Institute, ranging from those organized by the eighteen local centres to national conferences such as the Photographic Convention and the annual Congress which are of more general appeal. The meetings of the Institute are an important means of diffusing knowledge on photographic and professional matters and provide valuable opportunities for the interchange of ideas on topics of current interest.

The Institute publishes a monthly journal, *Record*, and has issued a series of documents on professional matters including *Standards of Practice for Commissioning Advertising Photography, Conditions of Engagement and Scale of Professional Fees for Commercial and Industrial Photography, Terms for the Employment of Professional Models, Fees and Conditions for granting Reproduction Rights in Copyright Photographs, Insurances for Photographers and Job Evaluation for Industrial Staff Photographers.*

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

The Institute also issues a *Register of Incorporated Photographers*, and a manual entitled *The Professional Photographer in Practice* has recently been published under its auspices.

Membership, which is worldwide, is open only to those persons professionally engaged in photography or an ancillary occupation and admission may be gained either through the examination system or under what are termed the Direct Entry regulations which require the submission of work.

The examinations of the Institute are held at three levels and all have a strong practical bias. Associateships and Fellowships have been awarded by the Institute since 1938 and those holding these titles are entitled to the designatory letters A.I.I.P. and F.I.I.P. respectively.

INSTRUMENT RECORDING. Photography offers a convenient means of recording the readings of scientific instruments. It releases the human observer, and at the same time provides a permanent record of the readings of every instrument throughout the duration of the experiment.

There are two principal ways of recording instrument readings with photographic material: dial instrument records—e.g., photographs taken of the normal instrument dials; and trace records—e.g., of instruments in which a moving spot of light takes the place of the calibrated dial and pointer.

Dial Instrument Record. The instrument dials are grouped closely together and a cine camera fitted with a wide angle lens is focused on them so that they fill the negative area. As a rule the aim is to read the instruments at regular intervals over a long period of time. This is done by setting the shutter release of the camera for single shot working and making the exposures by means of a solenoid-operated shutter release energized at regular intervals by a contactor clock.

The instrument dials are illuminated by diffused lighting so that the pointers do not case confusing shadows, and the light sources are placed so that they are not reflected in the dials. Where possible the glass is removed from the front of the instrument to reduce the risk of reflection of either the light source or the camera itself in the polished surface.

The dials are preferably finished in dead black with white figures and pointer as this combination gives a clear image and less risk of trouble with reflections.

If the exposures are made at fairly short intervals, the lighting is left switched on all the time. This is wasteful if the exposures are made at intervals of an hour or so. In this case the solenoid is equipped with switch contacts to switch on the light just before the shutter itself is tripped by the mechanism; the entire operation is then automatic.

The whole set-up is enclosed to keep out extraneous light and enable a standard exposure to be given.

If the instruments can be strongly lighted, microfilm is used for its high resolution; this is specially necessary when there are a large number of instruments in the picture.

Self-Contained Units. Very often the camera has to record instruments inside a self-contained piece of apparatus out of reach of a power supply—e.g., in a meteorological balloon. In this case the power for lighting the instrument dials and driving the camera is supplied from a small storage battery. If the test is to last for a long period, the camera may be operated by clockwork to save the drain on the battery. The battery can be made to last even longer by cutting down the power of the illumination until it just gives a readable image on the fastest panchromatic film. This is only possible when the grain of the emulsion does not make it difficult to read the instrument to the required degree of accuracy.

In self-contained units of this type, the size of the unit is kept down by using an arrangement of mirrors to give the required optical separation between the lens and the subject within the space available. The mirrors are of the surface silvered type to avoid getting double images with each mirror used.

Trace Records. Photographing normal instrument dials is at best a make-shift arrangement that is only justified where the instruments are already performing a distinct function—e.g., for records of the instrument panels in an aircraft. Where the sole purpose of the instruments is to provide a permanent record, it is far more satisfactory to get rid of the dial and substitute a moving light spot for the pointer. The light spot can then make its own record directly on a moving strip of sensitized film or paper without any need for a camera. If necessary, the moving elements of a number of instruments can be grouped to record simultaneously on the same piece of sensitized material. Or each instrument may make a separate record.

How the light spot is produced depends upon circumstances. In the simplest case the moving element of the instrument carried a mirror. A narrow beam of light falls on the mirror and is reflected on to the sensitized material. When the mirror rotates, the light moves across the sensitized material and leaves a developable trace.

The light trace may also be produced in a cathode ray tube. In this case its movement may be recorded directly on sensitized material, or it may fall on a fluorescent screen and leave a luminous trace for camera recording.

Instrument records of this type, where the instrument is specially designed for the purpose, are made nowadays inside projectiles and in other places unsuitable either a human observer or conventional instruments. F.P.

INSURANCE

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

In so far as a camera, with its appurtenances, is part of the equpment of a professional photographer's studio it will be insurable with the stock in trade, fixtures, fittings and other contents of the studio.

Similarly, the camera in private ownership is insurable with furniture, clothing and personal effects in the owner's private dwelling house or flat.

In both cases it will be insured whilst in the premises described in the policy against such perils as are fully set out in the policy itself.

Householder's Policy. The ordinary householder's policy does not insure a camera for more than 5 per cent of the declared full value of the contents. So the owner of a valuable camera, or, say, a cine-projector, should make sure that the value of each separate article in his photographic equipment does not exceed 5 per cent of the full value of the contents of his house. If it does, he must so declare it, have his equipment specially described in the policy of insurance, and insured specifically for such amounts as he considers reasonable.

This means that if the total contents of his house are insured for £2,000, a camera or other item of photographic equipment valued at more than £100 should be specially insured.

A comprehensive policy on the contents of a private house or flat provides for the temporary removal of personal effects, including cameras. Up to 15 per cent of the total value of the contents will be held insured against a limited number of perils while temporarily removed to other dwelling houses or other buildings in which the owner or his family may be residing. In other words, when the owner goes off on holiday the things he takes with him, including his camera, will be insured against certain risks whilst on the premises of the hotel in which he is to spend his holiday.

But fifteen per cent of the total value of the contents of a house does not go very far if the owner's wife has packed her smartest frocks, a few of her best furs and a selection of her choicest jewellery. There will be very little left of the permitted amount of insurance to take care of expensive cameras.

Note also that ordinary insurances are restricted to stated locations. The camera is insured only while it is in the house or flat, in the studio, or in the hotel.

All Risks Insurance. The operator often takes his apparatus to the scene which he wishes to photograph, and, unless he is a studio-portrait photographer, cannot wait for his subjects to visit him. The real need of the camera owner is a form of insurance which will protect his camera against loss or damage, anywhere.

This is available. It is known as "All Risks" insurance, but although its name implies that every form of loss or damage is covered, this is not strictly true. It does not cover wear and tear, mechanical breakdown, or electrical defects. It may exclude customs confiscation or detention. It sometimes excludes theft from unlocked motor cars. Loss or damage by rioters, strikers, and other forms of malicious damage are usually excluded, as is all damage or loss occasioned by war, invasion, foreign enemy and the like. Earthquake (outside Britain), or looting or pillage following earthquake, are other excluded perils.

These exceptions apart, the purpose of an All Risks insurance on cameras is to provide insurance protection against loss or damage, however and wherever caused. It may contain a clause which provides that the owner shall bear a small share—usually ten shillings or so—of claims in respect of damage to flash bulbs, which are particularly susceptible to damage, and special clauses dealing with damage or breakage of lenses are sometimes encountered.

Premium rates vary within fairly wide limits. Amateur photographers can obtain All Risks insurance on a camera worth £50 for as little as 10s. 6d. per annum if the cover is restricted to the United Kingdom, but for world-wide policies required by professional and press photographers, annual premium rates will rise to as much as 45s. per cent of the value of the apparatus to be insured.

In the United States of America the average premium rate is $1.50 per annum per $100 value insured. Usually there is a premium discount over a 3-year period, with an effective rate of 2½ times the annual rate.

Valuation. It is desirable that the camera or other equipment should be independently valued before it is insured. Apart from determining the real value of the camera, it enables the owner to describe it accurately. This description is of great importance if the camera should later be lost or stolen.

It is important that the full value of the equipment should be insured, because the policy usually contains an average clause. This provides that in any case where the value of any camera or apparatus exceeds the sum insured on it, the insured will be considered as being his own insurer for the difference between the real value and the sum insured, and shall share the loss accordingly. It is sometimes possible, by arrangement with the insurance company, to have this clause deleted, but only if the company is satisfied that the full value of the photographic equipment is insured.

Claims. The policy of insurance is a contract of indemnity. This means that the insurance company or underwriter undertakes to make good, by cash payment, reinstatement or repair, the intrinsic loss suffered by the owner as a result of the loss or damage from the insured peril. It is not an undertaking to pay a stated sum: the amount payable is measured by the extent of the loss suffered, with a maximum of

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

the sum insured which is set out in the policy itself.

If there should be any dispute between the parties about the settlement of a claim under the policy, it is referred to the decision of an arbitrator, and the policy contains an arbitration clause which fully protects the interests of both insured and insurer.

It is rare for the arbitration clause to be invoked. Claims usually are negotiated by independent assessors, who do not hesitate to enlist the services of experts when dealing with losses of such specialized property as photographic equipment and cameras.

All Risks insurances on cameras and photographic equipment are transacted by a number of insurance companies and by underwriters at Lloyd's. The office or offices handling the ordinary insurances of the photographer, either amateur or professional, will generally quote for his camera insurance, or will at least put him in touch with an insurer transacting the business.

Plate Glass Insurance. Apart from the insurance of his cameras and photographic equipment, there are other risks against which the owner of a professional studio should seek insurance protection.

If the studio forms part of the ground floor of the premises, it is more than likely it will have display windows, and the accidental breakage of the plate glass in windows, doors, fanlights and other parts of his shop front as well as neon signs, glass counters, display cabinets, and the like should be covered by insurance.

Motor Car Insurance. The motor car used by a professional photographer to make visits to the scene of his operations must be insured to conform with the provisions of the Road Traffic Acts, but the compulsory cover prescribed by law is restricted to insurance against liability for personal injuries to third parties. It is desirable that motor vehicles should be insured in such a way that the third party indemnity is extended to cover damage to the property of third parties as well as injuries to the person. Accidental damage to the motor vehicle itself should also be insured, including damage by fire, loss or damage by theft, and malicious damage as well as risk of injuries to passengers.

Motor insurers provide what is known as a "comprehensive" policy which is wholly admirable. It gives wide cover and deals effectively with the hazards of motoring. It should be noted that mechanical breakdowns of motor cars are not normally insurable.

The professional photographer who uses his private car for professional purposes is advised to examine his existing motor insurance policy, and in particular, the certificate of insurance which is issued to him by his insurance company. A motor car used solely for social, domestic and pleasure purposes is insurable at a lower rate of premium than one used for professional purposes. And while it is true that the user of a private car who insures it as such is permitted in the terms of his policy (and certificate of insurance) to make what are called "business calls in person", it is unlikely that a private motor car used for the purposes of a professional photographer is insurable at "private car" premium rates.

Where the car owner merely uses his car to take him to and from the studio, this will be treated as "private purposes", and the lower premium rate will be charged, but if, in addition, he uses his vehicle to visit churches to take the inevitable wedding group photographs, if, in fact, his motor car is used to convey apparatus and operator to places where work is to be done, the motor car should be insured as a private car used for business purposes and the appropriate premium for such use paid.

It is a serious offence at law to use a motor car on the roads without proper insurance, and the importance of ensuring that motor vehicle insurance is in order cannot be over-emphasized. Any photographer who allows an employee to use his car for business should see that the employee is correctly insured and, of course, that he holds a current driving licence.

Liability Insurance. Other forms of insurance to which the professional photographer should give attention include the important "liability" insurances.

As an employer he is liable at common law for the consequences of injuries to people in his employment caused by his negligence. He is also liable for injuries to people in his employment caused by the negligence of their fellow employees. To deal with this liability he must take out an employer's liability policy. This will cover all his employees, both regular and casual, and a modest premium based on the total wages expended in each year is charged for cover which fully meets all contingencies under this heading.

Apart from liabilities to employees, the professional photographer owes duties to members of the public, to the people who visit his premises as clients or otherwise and to the people who pass by. He is required to exercise reasonable care in the practice of his profession so that no harm shall come to them through his negligence. His studio must be maintained in a safe condition, well lighted, in proper repair, and when he, or members of his staff, leave the studio on "outside" work, care must be taken to see that no damage or injury is done to third parties even when the latter do everything possible to impede photographic work by crowding in on the subject.

These public, or Third Party liabilities, are taken care of by public liability policies which usually contain a limit of indemnity in respect of any one accident. As awards in damages by the courts to injured third parties are tending to rise, it is unwise to fix the limit of indemnity at less than £25,000.

A.S.W.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

INTAGLIO PROCESS. Photomechanical printing process in which the printing area of the block is incised into the metal and the non-printing areas stand up. When the block is inked up and then wiped off, the sunk areas are left filled with ink which prints as an image when pressed on to the paper. The most common example of this is photogravure.

INTEGRAL TRIPACK. Set of three emulsions and a filter layer coated on to a single film and used for making subtractive negatives or transparencies in an ordinary camera, or for colour prints when coated on a white base.

See also: *Colour film principles; Colour materials.*

INTEGRATING EXPOSURE METER. Meter which adds up the amount of light coming from the scene during exposure; all other meters measure the amount of light received at any one instant and, if the amount of light varies, the meter reading varies with it. Integrating meters can only be used for making long exposures, therefore they are not much used by the ordinary photographer. They are employed principally in process work where exposure times often run into many minutes and where arc lamp illumination may vary considerably during the period of exposure.

The term is also sometimes applied (incorrectly) to ordinary reflected light meters and sometimes to incident light meters, by virtue of the fact that both these meters "integrate" the light reaching them from a wide angle and give an average reading. The use of the term "integrating" is confusing in this connection and therefore best avoided.

See also: *Actinometer.*

INTEGRATION TO GREY. Principle of assessing the colour balance of a colour negative for printing. It assumes that the overall colour of average subjects in nature is more or less white or grey. This implies that if the colours in the image formed by an outdoor subject are completely mixed up (e.g. by complete diffusion) the result would be a fairly neutral colour tone.

The principle is applied in automatic colour printing, where the intensity of the red, green and blue components of completely diffused light derived from a colour negative are measured. The measurements are related to the red, green and blue content of the printing light to establish the required exposures (or the necessary printing filter pack) to yield a correctly balanced print.

In practice not all subjects integrate to grey. For example outdoor scenes showing large expanses of grass or woodland yield a predominant greenish tone on integration; a colour negative from such a scene, when printed by integration to grey, will therefore yield too magenta a print. Indoor shots including large areas of a single colour will exhibit similar anomalies. When printing such colour negatives, an over-riding allowance must therefore be made to obtain a correctly balanced print.

In integrating to grey, the measurements must also be taken with reference to an assumed outdoor colour balance. Under these conditions indoor scenes taken by artificial light or flash need a different allowance in integration.

See also: *Colour printing technique.*

INTENSIFICATION. Process of strengthening a photographic image which is too weak to give a satisfactory picture. It is possible to intensify both positive and negative images.

Negatives. Most methods of chemical intensifying either add another metal to the silver image, or make the image less transparent to actinic light. In either case the effective density increase is proportional to the existing density of the image. So the highlights are intensified more than the shadows and the over-all contrast of the negative is increased.

No chemical intensification can add much density to very faint images, and it cannot therefore greatly improve under-exposed negatives.

Most intensifiers (except perhaps silver) increase the image grain.

Chromium Intensification. Chromium intensification consists of first bleaching the image, and then redeveloping it. Bleaching is carried out in a halogenizing bath containing potassium bichromate.

Stock solution A		
Potassium bichromate	½ ounce	12·5 grams
Water to make	10 ounces	250 c.cm.
Stock solution B		
Hydrochloric acid concentrated	½ ounce	12·5 c.cm.
Water to make	10 ounces	250 c.cm.

The working solutions depend on the degree of intensification required as follows:

CHROMIUM INTENSIFIERS PROPORTIONS

Intensification	*Proportions of* A	B	Water
Slight	10 parts	10 parts	5 parts
Medium	10 parts	4 parts	11 parts
Strong	10 parts	2 parts	13 parts

The negative is left in the working solution until it has bleached right through and turned yellow-buff. It is then rinsed in a 2·5 per cent potassium metabisulphite solution, until the yellow stain has completely disappeared. It is then rinsed in water and transferred to a 3 per cent borax solution. Finally, the negative is redeveloped in an ordinary (not fine grain) metol-hydroquinone developer.

Mercury Intensification. In mercury intensification the image is first bleached and then darkened.

CC-0. Agamnigam Digital Presevation Foundation, Chandigarh

INTENSIFICATION. This consists of adding density to the image by chemical action, and usually increases also the over-all contrast of the negative. The density can only be added to existing image areas, not to clear parts.

The bleach consists of a 2·5 per cent mercuric chloride solution containing about 1·5 per cent hydrochloric acid. After bleaching the negative is rinsed in three or four successive baths of 3 per cent hydrochloric acid (a few minutes in each), washed in water, and then treated with a suitable darkener.

A number of chemicals are capable of darkening the image. Those below are arranged in order of increasing intensifying power:

(1) A 10 per cent sodium sulphite solution.

(2) A normal metol-hydroquinone or amidol developer.

(3) 0·880 ammonia solution diluted 1 : 20.

(4) A 2·5 per cent solution of sodium thio-antimoniate (Schlippe's salt) containing 1 per cent ammonia.

(5) A 1·5 per cent sodium sulphide solution.

(Both the mercuric chloride and the sodium thiosantimonate are intensely poisonous.)

Mercury intensification is uncertain and it does not form a permanent image.

Silver Intensifier. This is really a physical developer used on the fixed film. It does not appreciably increase the negative grain.

One of the earliest formulae was that of Wellington which used a mixture of silver nitrate, ammoniun thiocyanate, and hypo, with pyro to trigger the reaction. A more modern and cleaner formula is the following:

Stock solution A		
Sodium sulphite, anhydrous	2 ounces	50 grams
Distilled water	40 ounces	1,000 c.cm.
Stock solution B		
Silver nitrate	2 ounces	50 grams
Distilled water	40 ounces	1,000 c.cm.
Stock solution C		
Sodium thiosulphate, crystals	4 ounces	100 grams
Distilled water	40 ounces	1,000 c.cm.
Stock solution D		
Metol	140 grains	8 grams
Sodium sulphite, anhydrous	88 grains	5 grams
Distilled water	40 ounces	1,000 c.cm.

For use, stir 1 part of A slowly into 1 part of B and add 1 part of C. The white precipitate first formed should dissolve at this stage. Then stir in 4 parts of D. Immerse the negatives until sufficiently intensified, and then leave in a 20 per cent plain fixing bath for about ten minutes before washing. The working solution of the intensifier does not keep.

Toning Intensifiers. It is possible to intensify a negative image by sulphide-toning it by the method used for toning prints. Here the intensifying effect is partly the result of turning the image yellow and thereby making it much more opaque to the active rays in the printing light. The toned image is permanent.

Negatives can also be intensified in this way if the image is coloured by dye-toning it with a red dye, or by developing the bleached negative in a colour-coupling developer for red.

Optical Intensification. Apart from changing the silver image of the negative chemically, very thin negatives can be copied in such a way that the visual effect of the image is enhanced. This involves re-photographing the film or plate by low-level side light or dark-ground illumination. The individual silver grains, though not producing sufficient density to record tone detail on printing by transmitted light, then strongly scatter the illuminating light and so show up a reasonably strong image. This is particularly distinct if the silver is first converted to silver halide by a suitable bleaching process. The negative image then appears as a positive, and on re-copying yields a further negative of improved density and contrast.

An alternative way of optical intensification uses a complex reflecting system that directs the light to and fro through the negative up to five or more times before the light beam reaches the printing paper. During each passage through the negative the optical image is thus reinforced to show up improved density and contrast. Owing to the requirements of such a set-up, the multiple reflection leads to some loss of definition.

Prints. Negative intensifiers like chromium and mercury, which actually add neutral image-density, can be made to work on prints. The results are, however, inferior, partly because the reducer usually has an effect on the image-colour, and partly because the print-image does not in any case offer much scope for intensification. Again, it is usually quicker to make a fresh print.

Staining and similar chromatic intensifiers which intensify the negative by changing its colour and thus making it more opaque to actinic light, are used as print-toners, but not for intensifying prints.

Certain toning processes themselves also intensify the original image. L.A.M.

See also: *Optical aftertreatment.*

Books: *Developing*, by C. I. Jacobson; *The Complete Art of Printing and Enlarging*, by O. R. Croy (both London).

INTENSIFIER, IMAGE. Term generally applied to photo-electronic systems which convert very faint optical images into more intense ones. The faint image is projected on to a photo-cathode; the electron streams emitted by the latter are amplified electrically to form a brighter image on a receiving screen or on the film.

See also: *Image amplifier.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

INTENSIFYING SCREEN. Foil or plate transparent to X-rays, carrying a substance that fluoresces when struck by X-rays or certain other invisible radiations. Used mainly in radiography in contact with the film which is much more sensitive to the visible light emission of the screen than to the X-ray beam. A given radiographic exposure therefore yields a greater image density—though the screen grain may reduce definition.

See also: *X-ray films.*

INTENSITY SCALE. Scale of exposures in which the steps differ in the intensity of the light received but not in the time of exposure—e.g., the scale resulting from exposing through a step wedge and not by subjecting each step to an increasing time of exposure at a constant intensity of illumination. This is the type of scale favoured for sensitometry.

INTERCHANGEABLE LENS. Lens system which can be removed from a camera to permit the use of alternative lenses of different focal lengths and/or apertures. Popular on better types of miniature camera, but also on many professional and nearly all technical camera systems.

See also: *Lens interchangeable.*

INTERFERENCE. As light is a wave motion the waves may be out of phase, with the "crests" of one set coinciding with the "troughs" of another from the same source. When this occurs, the light is extinguished. This most commonly occurs by reflection in a thin film; if its thickness is comparable with the wavelength of the light, light waves reflected from the back may be out of phase with light reaching the front, and interference will occur.

The anti-reflection coating of a lens produces an example of interference: the light rays reflected from the surface of the glass are out of phase with the rays reflected from the surface of the coating (the thickness of the coating is controlled to make this happen). The result is that the individual reflected rays cancel out and there is no reflection from the lens surface.

Interference commonly leads to the production of colours. If the light is initially white, only those wavelengths are extinguished for which the thickness of the film produces interference, and the residual light is coloured. Newton's rings are an example of this effect.

Lippmann's process for making colour photographs relies on stationary waves produced by interference.

See also: *Diffraction.*

INTERIORS. Photographing the interior of a building has much in common with the photography of architecture in general. The aim is to produce an acceptable representation of the scene as it appears to the eye, with no violent or apparently false perspectives, no featureless shadows and no "burned out" highlights.

Equipment. The most satisfactory apparatus, containing all the requisite movements, is the field or stand camera. Most of the modern 4 × 5 ins. cameras are based on the original design of the early stand camera, including swing back (both vertical and horizontal) and the independent front with swing, rise and fall. Cameras without an adequate rising front impose definite limitations and it is nearly always better to use a camera possessing all the normal movements.

A tripod which can be used up to a height of 5 feet 10 ins., or any intermediary height down to 2 feet, is of inestimable value. The lower positions facilitate the photography of details on the sides of table tombs, font bases and similar subjects situated at low levels.

When using roll film it is advisable to have three roll film holders. One should be devoted exclusively to interiors and very contrastive subjects, one for normal exteriors and similar well-lit subjects and the third for flat exteriors, tablets, ledger stones, and other shots lacking in contrast. Processing can then be adjusted to suit the particular requirements of each roll (e.g., for soft contrast subjects, increased development should be given).

Two small pieces of lighted candle or a pocket torch are useful for judging the extreme edge of the field where otherwise it would be too dark to focus visually.

Viewpoint. For general interiors it is as well to use as distant a viewpoint as possible, and the longest focal length that will include the required area of the subject. Where the space is confined and it is necessary to use an extreme wide angle lens close to the subject, the viewpoint must be selected with great care or else the perspective will be so violent that the resulting photograph will look more like a tunnel than a room.

But there are, of course, instances when the creative photographer can put to good use the wide angle technique, with its exaggerated perspective. Many examples of such work, where distortion of perspective is both obvious and at the same time pleasing, can be found in architectural books and journals.

The height of the camera is important: a low viewpoint gives a good ceiling or roof perspective but foreshortens the floor and vice versa. When photographing a low cloister, for

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

instance, where the interest is in the vaulted roof, a viewpoint about 2 feet from the floor with the lens well raised would show all the details in good perspective. Photographing this same view with the tripod extended and the lens below centre would produce a fine photograph of the floor, but the roof would be in such sharp perspective that its features would be lost.

To obtain correct drawing without appreciable distortion, only the centre of the field of the lens should be used, therefore the longer the focus of the lens in relation to the plate the better.

Lighting. Most interiors, with the exception of cinemas, theatres and other darkened buildings, can be photographed by natural lighting, but it is generally better to supplement it with some form of artificial light.

Large interiors—e.g., of a theatre or cinema—call for either a battery of 500 watt floodlights, a number of flash bulbs or a really large dose of flash powder. Flash powder is cheaper than bulbs, but it is advisable to use it only where there is a good extractor fan to suck the resulting clouds of smoke from the building.

Flash bulbs are the most convenient form of lighting, but for big buildings they are rather costly. Experienced workers often photograph large interiors by the light of consecutive flashes covering the whole field, but the flash position must be carefully chosen to prevent the result from looking patchy.

Flood lamps have the advantage that they allow the final effect to be judged before exposure. Also, flood lamps can be tied to a pole and hoisted aloft in dark church roofs. A suitable power-supply is, however, necessary.

Shops, showrooms and well lighted buildings can be satisfactorily photographed by their own lighting. Electronic flash is not as a rule powerful enough for general interiors, but can be very useful for close-ups and details.

When artificial light sources are used to supplement existing lighting or daylight, they must not be allowed to cast defined shadows, particularly when they are used to lighten up shadows in a photograph taken against the light.

Professional photographers are often asked to take factory or school interiors without interrupting the normal activity of the people present. A reflex camera with a four-way swing front, a *f*4·5 lens and a fast panchromatic plate form an excellent combination for this type of work. With brightly lighted subjects of this type it is often possible to give an exposure of 1/15 sec. at *f*11 even when photographing against the source of light. However, to get really good results, the photographer should have the building, and those present in it, under his control during the assignment.

Windows are difficult to reproduce by normal methods. If the exposure is long enough to show detail in the interior, it over-exposes the windows and reproduces them as blank areas of paper surrounded by halation. The trouble can be partly cured by using fill-in lighting for the interior.

Sometimes it is possible to set up the camera and make an exposure in daylight for the windows only, making a second exposure for the interior by artificial light after sunset. Where the camera can be left undisturbed for the required time, this is an excellent way of solving the problem.

Setting Up. The camera is set up at the chosen viewpoint and adjusted to give a sharp image over the required depth of field, with all vertical lines parallel to the sides of the picture and all horizontal planes in satisfactory perspective. Where the camera has no camera movements, it may be necessary to accept some distortion which it may be possible to correct in part during enlarging.

Focusing. Focusing follows the pattern for normal photographs of architecture—that is, everything should be critically sharp (except when special effects are required). Particular attention should therefore be paid to depth of field, ensuring that the lens is stopped down sufficiently to render every plane in the subject sharp.

When photographing interiors the vertical swing front is used more than when taking the outsides of buildings. Flights of stairs, for instance, call for vertical swing to bring the whole length inside the depth of field of the lens. while details of floors and roofs are much easier to record with the aid of this camera movement.

The relatively poor lighting of interiors is apt to make focusing difficult. But it is quite easy to focus on a small electric torch, or even a candle flame held by an assistant or simply propped on a table or chair.

When it is impossible for the photographer to get behind the camera to focus, the method of working is simple: he measures the distance from the subject to the position of the camera. Then he focuses on a piece of printed matter at a similar distance from the camera, in a place where he can conveniently view the screen. The next step is to put the camera into the required position. The subject is now sharply focused on the film.

Sensitized Materials. As it is often desirable to give individual development, sheet films and plates are preferable to roll-films. With roll films and tank development control of gradation is confined to choice of developer and development technique.

With interiors in particular, it is unlikely that a roll film would give a series of negatives that would compare with the same subjects photographed on a dozen sheet films and developed individually.

Medium speed panchromatic plates are ideal because they have a fine grain and the contrast can be regulated by varying the length of development. They should, of course, have anti-halation backing.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The best plate for architectural interiors is the double coated type consisting of a fast emulsion coated on a slow orthochromatic emulsion. These plates lend themselves to the abnormal contrasts so often encountered when photographing the inside of buildings where light sources—windows or artificial lights—appear in the picture.

Exposure. When photographing interiors, a photo-electric exposure meter is invaluable, although the photometer type of meter, with its narrow acceptance angle which makes it possible to take an accurate reading on an isolated shadow, can be even more useful.

With interiors the reading of any type of meter must be regarded as a guide and not an infallible indication. It is generally safe to take the meter reading on the darkest part of the subject (the roof of the building or its darkest corner) and then multiply the exposure indicated by 3. When photographing details against a contrasting background—e.g., bronze statuary against white marble—the meter should be read close up to the subject to exclude the effect of the background.

Stained glass windows can generally be well rendered by measuring the exposure necessary to photograph them from outside, and giving from 6 to 10 times this exposure inside. This generous exposure, followed by development curtailed to one-third the normal time for general interiors, will give excellent negatives.

For dark woodwork detail it is practically impossible to over-expose, but great care must be taken in developing to avoid high contrast, otherwise the highlights will print white and the shadows black instead of in proportionate tones of grey.

As a very rough guide for general interiors where the lighting is normal, using a medium speed material and a stop of *f* 32, an exposure of well under 30 seconds should be ample.

With architectural interiors, the old rule of exposing for the shadows and developing for the highlights will nearly always prove to be reliable.

Development. Development calls for just as much care as exposure: the aim in the one case is to give enough exposure for the shadows to show detail, in the other case to give enough development to show detail in the highlights but not so much that they become clogged and look "burned out" in the print.

The sort of negative aimed at is one which will give a full scale of tones when printed on normal bromide paper. L.H.-F.

See also: *Architecture; Camera movements.*

Book: *Basic Photography*, by M. Langford (London.)

INTERMITTENCY EFFECT. Phenomenon met with in sensitometry having reference to the fact that a large number of brief separate exposures do not produce the same effect on the sensitive material as the theoretically equivalent single exposure.

INTERNATIONAL CANDLE. Basic unit of illumination: the light output of a spermaceti wax candle burning at the rate of 120 grains of wax per hour.

See also: *Light units.*

INTERNEGATIVE FILM. Specially designed type of colour negative film adapted for the production of colour prints from colour transparencies. Such colour prints may be either on paper base or on clear film base. In the latter case the resulting product is a further colour transparency which may be either the same size as the original or an enlargement or reduction. To avoid the inevitable loss of colour saturation associated with copying colour transparencies, modern internegative film generally incorporated built-in coloured coupler masking.

Although it is generally desirable in copying or printing colour transparencies to maintain or even lower the overall contrast of the process, the contrast of the highlight parts of the subject will need to be maintained or raised. This requirement results naturally from the shape of the normal characteristic curve of photographic sensitive materials. One commercially available internegative film maintains the overall contrast of the copy negative by producing a characteristic curve with the required slope in the mid tones but enhances the contrast of the highlights in the copy. To accomplish this, the characteristic curve of the internegative material has a shoulder of increasing gradient in place of the more usual decreasing gradient.

With such a material incorporating both coloured coupler masking and tone scale correction excellent colour prints and duplicate transparencies can be made from colour slides.

INTERSECTION OF THIRDS. Popular art term decribing the division of the picture area into thirds by two horizontal and two vertical lines. The points where these lines cross have been claimed to be particularly suited for placing the picture's "centre of interest". This recommendation means, of course, turning into an over-simplified positive assertion the truth that neither a strictly symmetrical position nor one near the edges is likely to be the best for most subjects.

See also: *Composition; Golden section (secto aurea).*

INVERSE SQUARE LAW. When a surface is illuminated by a point source of light, the intensity of illumination produced is inversely proportional to the square of the distance separating them.

This is the law of inverse squares; it is easier to understand from a practical example. If the distance between the light and the surface is doubled, the intensity of illumination is reduced to one quarter; at three times the distance, it is reduced to one-ninth and so on.

See also: *Illumination.*

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

INVERTED TELEPHOTO LENS. Lens designed to have a short focal length but a relatively long back focus—i.e., a short focus lens which works at a relatively long distance from the plate. The construction consists of a group of diverging lenses followed by a converging group.

Lenses of this type are used in one method of colour cinematography where room must be left between the lens and the film to accommodate a prism system.

See also: *Wide angle lens.*

INVERT (INTAGLIO) HALF-TONE. Photomechanical reproduction process similar in some respects to photogravure. The image is etched into the cylinder to comparatively equal depth and the tones are produced by a half-tone dot formation. The Dultgen process is a well-known form.

INVISIBLE RAYS. Visible light forms only a small proportion of the range of electromagnetic vibration. The whole range extends from radiations with a wavelength of several miles to those with a wavelength of less than a hundredth of an Angstrôm unit (one ten-millionth of a millimetre).

Over this immense range of radiations only a small fraction (from about 4,000 A to about 7,000 A—i.e., violet to red) is visible as light.

Above and below the visible spectrum the radiations take the form of invisible rays. Below—i.e., longer than—the visible red rays there are infra-red, heat, and "wireless" waves, all of which are invisible. Above—i.e., shorter than—the visible violet rays, there are invisible ultra-violet rays, X-rays and gamma rays.

Some of these forms of radiation—e g., the infra-red, ultra-violet, X- and gamma rays—although invisible, are able to produce a developable image in a photographic emulsion. Furthermore, these radiations all behave in characteristic ways which differ from visible light—e.g., X- and gamma rays will penetrate opaque objects, ultra-violet rays cause certain substances to fluoresce visibly, and Infra-red rays will penetrate fog and haze more readily than visible light.

Thus invisible rays can be utilized for certain types of photography that would not be possible with normal visible light.

Illustrations: Plate Section XV.

Book: *The Measurement of Optical Radiations*, by G. Bauer (London).

IODINE. Used in reducers and bleachers.

Formula and molecular weight: I_2; 254.

Characteristics: Black crystals. Attacks rubber and cork, therefore keep in glass stoppered bottles.

Solubility: Very slightly soluble in water, freely soluble in potassium iodide solutions, also in alcohol and ether.

IRIS DIAPHRAGM. Standard type of adjustable lens stop. It consists of a number of thin metal or vulcanite leaves arranged to form a roughly circular aperture. The aperture size can be varied by movement of a lever.

See also: *Diaphragm.*

IRIS MOUNT. Type of lens mount that stands out from the lens panel with the iris diaphragm adjustment well clear.

See also: *Lens mounts.*

IRON ALUM. Chemical used in some toners and reducers. Available as purple crystals which give a yellow solution.

See also: *Alum, Iron.*

IRON PRINTING PROCESSES. Various largely obsolete methods of making prints from negatives by the conversion of certain ferric to ferrous salts on exposure to light. Same as iron salt processes. Blue prints are made by an iron printing process.

IRON SALT PROCESSES. Photographic processes utilizing the action of light on ferric salts which are reduced to the corresponding ferrous salt. The latter acts as an intermediary in forming a visible image. Thus it can be converted into Prussian blue (blue print process) or used to reduce silver salts in the emulsion to silver (Kallitype and other iron-silver processes) or to reduce palladium or platinium salts (palladiotype and platinotype).

In a variation of the blue print process (Pellet process) the unexposed iron salts are converted into Prussian blue to form the image.

Yet another type of iron salt process is based on insoluble coloured compounds formed by ferric salts with gallic or tannic acid (ferro-gallic and ferro-tannic process).

See also: *Fabric printing; Ferro-prussiate process; Printing processes (obsolete).*

IRRADIATION. Rays of light falling on the sensitive emulsion tend to be scattered by reflection from silver halide crystals as they travel through it. This scattering effect is called

IRRADIATION. The scattering of light by the grains in the emulsion causes the image to spread sideways from the directly exposed area, resulting in a diffused surround.

irradiation; it is caused by the physical structure of the emulsion.

The effect of irradiation is to spread the image and destroy definition—i.e., it lowers the resolving power of the emulsion and is one of the reasons why thick emulsions have a lower resolving power than thin.

Irradiation increases the effect of halation—i.e., image spread caused by light rays scattered within the emulsion layer after reflection from the surface of the support.

The effects of irradiation can be minimized by processing emulsions in a surface developer. In this way, the image is confined to the surface of the emulsion and spreads less severely.

ISENRING, JOHANN BAPTIST, 1796–1860. Swiss painter, engraver, daguerreotypist and photographer. In December, 1839, Isenring produced daguerreotypes of his native town, St. Gallen, Switzerland, and from May 1840 took experimental portraits of friends. In July 1841 opened a studio in Munich. He was one of the first to retouch and colour daguerreotypes. Biography by E. Stenger (Berlin 1931).

ISOCHROMATIC. Term much used at one time to describe emulsions which were more or less sensitive to colours in proportion to their visual intensity. It covered many types of sensitized materials, some of which were sensitive to all colours, and some to only a part of the visible spectrum. It has now been dropped in favour of orthochromatic and panchromatic.

ISOTOPES. Atoms of an element having different atomic masses (i.e., different individual atomic weights). As long as they still have the same atomic number, they are chemically the same element and behave like it in practically all respects. They cannot be separated by normal methods of chemical analysis but only by physical means which depend on atomic weights. For example, heavy hydrogen (atomic mass 2) is an isotope of ordinary hydrogen (atomic mass 1).

Most elements have several natural isotopes. Artificial isotopes may be of photographic use as they are often radioactive. These are produced in an atomic reactor and are available as a convenient source of gamma rays. They are used in industrial radiography for the non-destructive testing of welds and castings.

See also: *Gamma radiography.*

ISRAEL. Photography came to the land of the Bible many years before the creation of the modern state of Israel. It played an important part in documenting the events leading to the establishment of the nation's statehood, and has been used to record the history of the last fifty years. Photographs were a publicity tool serving to inform the outside world of the events of the time, as well as of the aspirations which caused those events. The pictures had to be realistic enough to convince, and also sufficiently beautiful to catch the eye and fire the imagination of the viewer.

Industry and Commerce. No photographic equipment is manufactured in Israel although items such as studio tripods and light stands are sometimes built to special order. Bromide and gaslight papers are produced by two local firms, but they are not of the highest standard. Most foreign brands are now readily available, though prices are somewhat higher than abroad. Cameras and projectors displayed in the shops are mostly Japanese, U.S., German and Russian (available in that order).

Commercial photography is quite new and there are only three commercial studios worthy of the name in the whole country as yet. The first large scale D & P laboratory was opened in Jaffa only a short time ago. It accepts black-and-white work from all over the country, mostly through a chain of supermarkets. All photographic shops and most studios accept amateur work which they develop and print themselves. Most of the darkrooms are small, one-man affairs. Drugstores and chemists generally do not sell films nor accept D & P. Colour processing is done by some shops and at least one manufacturer's agent in Tel Aviv accepts Kodak film for processing in the U.K.

Exhibitions and Archives. Photographic exhibitions are held from time to time, and are usually one-man shows. Most take place at the Artists' Club, Jerusalem, or at the Journalists' House, Tel Aviv. A few competitions have been sponsored by the Prime Minister's Office, and the entries exhibited to the public.

Today the Jewish Agency's Jerusalem office contains the greatest photographic archive in the country, some 75,000 negatives including work by Kluger, Lerski and other masters. Another large photo archive is that of the Government Press Division's Tel Aviv office. It was started in 1948 and now contains about 50,000 negatives. Both these archives serve the general public for a nominal fee.

Associations. Photo-journalists are organized in the Irgun Tsalamei Haitonut (Press Photographers' Union), which is very exclusive. Illustrated magazines buy pictures from all sources, although Government Press Cards are distributed only on recommendation by the Union.

Studio owners belong to the Igud Baalej Melaha (Artisans' Organization), while the Igud Hasoharim (Dealers' Organization) represents photographic retailers.

There is little contact between amateurs, photo-journalists and portrait photographers. Amateurs are numerous but quite unorganized. So far all attempts to start photo clubs have been short-lived.

Training. Little proof of qualifications is required of newcomers to the trade and formal

CC-BY-NC-SA. Digital Preservation Foundation, Chandigarh

training is rare. When a high demand for photographers was felt, the Government sponsored, in 1960, a two-year course for photographers' assistants in Jerusalem. One school for girls, at Haifa, also runs photographic courses.

Publications. The two million Israelis read about 150 illustrated magazines including one for women, three movie journals and three armed service magazines (published by the Army, Navy and Air Force). There are also publications on electronics, architecture, engineering, motoring and the theatre. There are some weeklies of general interest in Hebrew as well as in numerous foreign languages. Many of these employ staff photographers, but all accept freelance work when suitable matter is offered.

Photographic magazines on the news stands include many publications from the U.S.A. and Great Britain. Photographic literature is available mostly in English, German and French.

Photography Today. Visitors to Israel will find a diversity of subject matter. The beaches of Tel Aviv and the long Mediterranean shore are a photographer's paradise. Antique ruins and statuary are to be found at most historical places mentioned in the Scriptures. Many villages are peopled by new immigrants from some seventy countries, who still live according to their native customs and frequently wear the costume of their country of origin. Roughly half of the country is desert land, roamed by Bedouin and their herds of sheep and cattle. Eilath on the Red Sea offers the world's best underwater photography. The Government Tourist Office publishes a weekly information booklet on festivals of interest to the tourist. It is distributed free at hotels and Tourist Information Centres.

It should be borne in mind that the light in Israel is harsh, with exceedingly black shadows and blinding highlights, and thus many newcomers under-expose their black-and-white pictures and over-expose their colour slides.

During the three months of winter, December to February, torrential rains may be expected and these constitute a real danger to equipment. The hot winds of spring and autumn make films and paper curl up, and load them with static electricity. These winds also carry, from the Arabian desert, sand which can penetrate even tightly closed camera bags. It is therefore a good idea always to have some polythene bags ready, in which to stow equipment and films against rain and wind.

In the heat of summer, cameras and films should be kept out of the sun (and such places as a car's glove compartments) as much as possible. Colour films should be kept in refrigeration unless used within a few weeks, and processed as soon as possible after exposure. Films should be removed from the refrigerator a few hours before shooting to avoid condensation of moisture, and cans should not be sealed airtight after exposure.

Visitors should bear in mind that orthodox Jews object, on religious grounds, to being photographed, and Bedouin frequently expect a tip for posing. Certain military installations must not be photographed, and these are marked clearly by signboards in both Hebrew and English.

W.H.

ITALY

Photography in Italy has roots which can be related to the sixteenth century. At that time, the camera obscura, the origin of which is very remote, was described by Leonardo da Vinci in the *Codice Atlantico*. Later, in 1568, the Venetian nobleman, Daniello Barbaro, improved it by putting a lens where there had formerly been a small hole through which passed the rays forming the image. The scientist, G. B. della Porta of Naples described it in his book *Magia Naturalis* (1558) and as a result its invention was often wrongly attributed to him. Nevertheless his name has always been linked with the history of the camera obscura as he made it widely known.

In the early days of photography proper, daguerreotypes were made in Italy, but few details are available as at the time Italy was split up into a number of small states which were not united until 1870.

Already, about 1853, there were excellent photographers, some using the collodion process, others albumen, among them Luigi Bardi in Florence, Ponti in Venice and Anderson in Rome—(the firm established by Anderson still exists today). At about this period, Robert MacPherson worked with great success for over twenty years in Rome. The Alinari brothers established a considerable business in Florence in the 1850s with views and architecture, later reproducing on collodion plates the principal works of painting and sculpture in Florence, Rome, the Vatican and elsewhere in Italy.

At the beginning of the present century they opened a collotype establishment for printing three-colour reproductions of the principal paintings in Italy, which have been exported throughout the world.

Italy has had some outstanding photographers. Typical of these was Sella, who produced excellent mountain studies on collodion plates with a telephoto lens. He was attached as official photographer to a number of high mountain expeditions including the Himalayan expedition to Karakorum (K2) led by the Duke of Abruzzi, and to Alaska, the Caucasus, etc.

Pesce of Naples had an excellent collection of historic cameras and lenses. Other equipment or parts, both photographic and cinema-

tographic, are on display in the Milan Science and Technology Museum.

The Italian photographic industry started its activity in Milan during 1886, thanks to Michele Cappelli. During the first Italian Photographic Exhibition held in Florence in 1887, the dry silver bromide plate was presented to the public and placed on the market. Approximately 20–30 sq. metres of plate were manufactured daily during the first years, while as early as 1910 the daily average had reached 300 sq. metres. After passing through the austerity of the war period, and its shortage of glass supplies, the daily production of plates increased to 500 sq. metres in 1926. The manufacture of printing paper in Italy dates back to 1905, and by about 1914 100,000 sq. metres were produced monthly. Two plants for the manufacture of photographic and cinema films were established in 1919 at Ferrania, a locality among the mountains near Savona. One manufactured the celluloid base and the other the emulsion. The true and proper manufacture of photographic and cine negative and positive film started after 1920. Industrial production of radiographic films, filmpacks and 16 mm. sub-standard films started between 1926 and 1930. Colour films and paper for colour prints have been produced since 1949.

According to a survey carried out among the middle classes, 60 per cent of Italian families own a stills camera, and 6 per cent have a movie camera and projector. Of the films used for stills photography, 42 per cent are made in Italy.

The number of photographic dealers has greatly increased since the late war and now totals over 5,000. They are supplied by about thirty-five wholesalers. Very few of these dealers are now equipped to do their own finishing; they call on the services of numerous independent photo-finishers, some of whom are fully equipped for colour.

Professional Training. At present, twelve schools of photography offer professional training to those who intend to take up photography as a career. Half of these are state-run while the others are private concerns. The State schools include those of Milan, Turin, Florence and Rome, where the courses last seven years, while in the others the period of study ranges from 2 to 4 years. Once they have their diplomas, the students from these schools easily find good jobs, particularly in large concerns with photographic laboratories. However, no one wishing to set up in business as a photographer is required to produce evidence of his qualifications or general education, but only needs to fulfil certain formalities of an administrative character. There is no organization linking professional photographers together for technical or instructional purposes.

The number of professional portrait photographers has greatly decreased in recent years, while industrial, publicity, press and action photography has become correspondingly more popular.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

Amateur Clubs and Societies. The leading association of Italian photographers in the nineteenth century was the now defunct Società Fotografica Italiana (Italian Photographic Society) of Florence. Its president was the late G. Pizzighelli, who was well known for his researches in photographic optics and platinum paper. The society with the largest membership today is the Società Fotografica Subalpina (Subalpine Photographic Society) of Turin, which also dates from the past century. In the past five or six years there has been a considerable increase in the number of societies throughout the country, which now total 200, with an aggregate membership of over 9,000. They are particularly active in the organization of exhibitions. Many are autonomous, while others form part of the Circoli Ricreativi per i Lavoratori (Workers' Recreation Clubs) which have been formed for the employees of all the larger firms. The majority of photographic societies are affiliated to the Federazione Italiana Associazioni Fotografiche (Federation of Italian Photographic Associations). Two photographic societies broke away from the Federation with the declared aim of raising the standard of pictorial photography. One is now extremely active, especially in organizing exhibitions of members' work.

The older-established societies generally have large premises for meetings, and equipment for still and sub-standard cine projection; some also have a completely equipped darkroom for the use of members. Owing to the high rents now prevailing, most of the more recently formed societies have no proper headquarters, meetings being held at cafés and in members' own homes.

Publications. Five photographic journals, all monthly, are published in Italy. *Ferrania*, *Fotografia* and *Progresso Fotografico* in Milan; *La Gazzeta della Fotografia* at Palermo, and *Il Corriere Fotografico* at Turin. Italian editions of the West German *Foto-Magazin* and the American *Popular Photography* are also published. There are three news-sheets on photography: *Il Commercio Fotografico* (monthly) and *Punto Focale* (monthly) of Rome, and *Il Giornale del Fotografo* (quarterly) of Trieste. Three publishing companies specialize in books on professional and amateur photography. A.O. (C.M.)

Industry. The photographic industy in Italy is comparatively small and concerned mainly with the production of sensitized materials. The number of manufacturing establishments in operation in 1963 was approximately 25, with a total employment figure in the region of 7,500 persons. Of this figure, the equipment sector accounts for the majority of producers, whilst sensitized materials manufacturers number about half a dozen, although the two sectors have about equal numbers of employees.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The industry is principally located in Northern Italy, centring on Milan, whilst there are also several producers around Florence and Rome.

Among leading manufacturers of equipment is Bencini of Milan, producers of inexpensive still cameras particularly for export markets, Durst at Bolzano, well known for their enlarging equipment and also still cameras, and Ferrania Apparechi Foto, makers of still cameras and accessories. In the field of projection apparatus, the firms of Microtecnica and Silma, both located at Turin, produce cine projectors, whilst Malinverno, established at Milan, manufactures stilll projectors.

The sensitized materials sector is dominated by the Ferrania Company of Milan, makers of all types of photographic film and paper, whilst there are in addition a small number of manufacturers of plates and paper. In 1963, Ferrania had a sales figure of £17 million, and the number of persons employed was in the region of 4,700.

During 1964, Ferrania was acquired by the Minnesota Mining and Manufacturing Company of America, who also control Bauchet, the French film and paper producer.

Since the sectors of the photographic industry form only a minor part of the optical goods and chemical industries, separate statistics of production are difficult to obtain. However, the following figures have been estimated for the value of output over the last five years, and demonstrate the predominance of sensitized materials.

No breakdown of this data is available, but in the light of export statistics the production of cine projection equipment appears to be a leading activity among apparatus manufacturing. Sensitized materials have shown a moderate growth in output since 1959, among which cine film probably now accounts for about one-third of the total value, whilst X-ray film is also an important product.

Imports. Evidence of a growing domestic market for photographic goods is provided by the threefold increase in the value of imports which has taken place since 1959, reaching a total of Lire 21,214 million in 1963.

Almost half of the total is now accounted for by apparatus, among which still cameras are a leading product. The majority of these are of the amateur type (Lire 2881 million in 1963), the principal supplier of which is West Germany (Lire 1,772 million during 1963).

Imports of cine equipment have followed a sharply rising trend over the last five years, the larger part of which is attributable to cameras. Among these the 8 mm. type predominates, totalling Lire 2,382 million in 1963, the main sources of which were (in million of Lire), Japan (1,229), Switzerland (514), and West Germany (341). Cine projection apparatus is also composed mainly of 8 mm. gauge models (Lire 1,480 million in 1963), of which Austria supplied Lire 301 million's worth and Switzerland Lire 205 million's worth.

The leading place among imports of sensitized material is held by cine film, which accounted for 35 per cent of the Lire 10,932 million total in 1963.

The greater part of this item is supplied by France (Lire 2,032 million), whilst the U.S.A. (Lire 655 million), Belgium (Lire 577 million), and West Germany (Lire 509 million) are also important sources.

Plates and still film together form another main product among imports, totalling Lire 3,407 million in 1963, of which the roll film part was valued at Lire 2,203 million. France is the leading supplier of this, with Lire 816 million, whilst West Germany was responsible for Lire 603 million's worth and the U.S.A. for Lire 399 million's worth.

Another important material is sensitized paper, which has more than doubled in value over the past five years to reach Lire 2,966 million in 1963. West Germany is the principal source of this, with Lire 1,275 million during the year, whilst France supplied Lire 410 million, and Belgium Lire 485 million's worth.

Exports. The value of exported photographic equipment and materials has expanded two and a half times since 1959, to a total of Lire 13,418 million in 1963.

In keeping with the Italian industry's pattern of production, about a third of total exports is represented by apparatus, among which cine projection equipment holds the leading position. Exports of the latter more than quadrupled since 1959, reaching Lire 1,985 million during 1963, consisting of 16 mm. and larger gauge projectors worth Lire 1,257 million (of which the U.S.A. was the chief purchaser, taking Lire 329 million's worth), together with 8 mm. equipment totalling Lire 728 million (the principal market for which was France with Lire 135 million's worth).

Exports of cine cameras are small in comparison, and consist mainly of 16 mm. and larger gauge models. Still cameras, however, form an important item, the bulk of which are of the less expensive amateur type (Lire 272 million in 1963), the principal markets for the latter being the U.K. (Lire 84 million), and West Germany (Lire 62 million).

Among other still and cine apparatus, the largest group is composed of still projectors, enlargers and reducers, together totalling Lire 1,137 million in 1963, of which Lire 225 million reached the U.S.A.

Sensitized materials exported have shown a substantial rise in value in recent years to reach Lire 8,851 million in 1963. The most important product is cine film, totalling Lire 3,541 million during 1963, for which the largest single purchaser is West Germany, receiving stock worth Lire 1,485 million, whilst Yugoslavia took Lire 104 million's worth.

The other leading product group is composed of still film and plates, worth Lire 4,772 million in 1963, among which the largest part is due to

sheet film (Lire 3,683 million). The main purchaser of this latter material is France (Lire 819 million), whilst the U.S.A. (Lire 71 million) and West Germany (Lire 426 million) are also important markets. Among other items, roll film accounted for Lire 1,018 million during 1963, of which Yugoslavia received Lire 348 million's worth.

IVES, CHARLES, 1902–62. American photographic scientist and engineer. Pioneered research in motion picture engineering and developed new methods and techniques for rapid processing in high temperature solutions. From 1940, supervised the Photographic Chemistry Department of Eastman Kodak; 1956–7 member of the Department of Military Photography, and later Technical Staff Assistant to the Head of the Applied Photography Division.

IVES, FREDERIC EUGENE, 1856–1937. American photographer and inventor. Among his 70 U.S. patents are many concerning improvements in the half-tone process, the most important being an improved half-tone screen, 1885.

For colour photography with three separation negatives, Ives invented the Photochromoscope camera, 1891, and viewing instrument, 1892—later called Kromskop. He also brought out stereo versions of these, and the three-lens lantern Kromskop for projection in colour, 1895. Whilst his first colour camera worked with a repeating back, several later versions were one-shot colour cameras. Ives also invented a 3-D cine camera working on the Anaglyphic system, and the parallax stereogram process requiring no viewing instrument, 1903.

The latter was re-introduced after World War II as Vita Vision. Progress Medal of the R.P.S. 1903. Autobiography, Philadelphia 1928; biography by L. W. Sipley (Philadelphia 1956). H. & A.G.

IVORYTYPE. Photographic positive intended to imitate a painting on ivory. The method of preparation (no longer practised) was as follows. A print on plain salted paper was stretched face up on a sheet of glass and coloured by hand. The print was then impregnated with wax, stripped from the glass and squeegeed face down on to a hot sheet of polished glass. The paper base, then translucent (owing to the wax), was finally backed up with white or ivory-tinted paper.

The same name was sometimes applied to transparencies prepared by the Eberneum process, which gave a similar effect. This method was more troublesome and never achieved the popularity of the Ivorytype.

See also: *Eburneum process; Printing processes (obsolete).*

J

JANSSEN, PIERRE JULES CÉSAR, 1824–1907. French astrophysicist. Invented in 1874 a "photographic revolver" with focal plane shutter for the chronophotographic study of the Venus transit. Photographed the sun in 1877, the big comet of 1881 and sun spots in 1885. Worked on solarization (1880) and found in 1881 the reciprocity law failure. Received the Progress Medal of the Royal Photographic Society in 1906 "for his eminent services to photography, especially in its applications to solar and spectroscopic investigations".

JAPAN

Photography is used extensively in Japan in science and industry, and besides its normal commercial applications, it also has a very strong amateur following.

History. The first camera to be introduced into Japan was a daguerreotype apparatus brought through Dutch trade to Nagasaki in 1840 at a time when Japan's foreign commerce was limited almost wholly to that with Holland. A Nagasaki chemist, Toshinojo Ueno, acquired this daguerreotype outfit and began a study of photography, and today he is considered the father of photography in Japan.

Ueno's photograph of the powerful feudal lord Prince Nariakira Shimazu taken on 1st June 1841, in Kagoshima in southern Kyushu, is recorded as the first in Japanese history. The use of the camera for portraits and scenic photographs spread rapidly among the Japanese, who displayed considerable skill in the new medium of art. A number of students of photography emerged from among the great feudal lords, including Prince Shimazu and other nobles and leading scholars of the day as well as from among the common people, many of whom in the early period had regarded the new instrument with superstitious fear.

Photography spread in the various treaty ports and through the influence of the foreign residents until finally foreign trading firms and Japanese middlemen in Nagasaki and Yokohama began to deal in photographic supplies. Two major Japanese importers of photographic material were established by Tokichi Asanuma and Rokuemon Konishi, both of whom began as middlemen during this early period.

The pioneers in professional photography in Japan were Renjo Shimooka, who began his work in Yokohama in 1862, and Hikoma Ueno, who opened his studio in Nagasaki in the same year. Subsequently eminent pupils of these two pioneers began to attract attention, and with the advance of technical skill throughout the country photography developed into a highly respected profession and art.

During the Meiji Period (1868–1911) photographic research organizations were established by the Englishman W. K. Burton, Kazumasa Ogawa, Seibei Kajima and others.

This period saw the beginning of Japan's photographic industry and the first appearance of photographic publications. Amateur photography spread rapidly, and the foundation for today's popular and highly developed photographic culture, industry and profession was established. S.U.

Science. Photographic science and technical training have been incorporated in the curricula of such Japanese educational institutions as Kyoto and Chiba universities, where a photographic science department has been established. Tokyo Photographic Junior College has departments in photographic industry and photo-engraving, while the Chiba and Nihon universities offer motion picture courses.

Three of the four major photographic equipment and supply manufacturing companies in Japan maintain independent research laboratories, while the fourth has a research department. There are more than 300 independent

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

photographic research workers, among whom are a number of university professors and graduate students.

Only a few of the many camera manufacturing companies have their own research laboratories and their staffs are relatively small. However, the ability of the research workers in the lens-making companies and in universities is recognized throughout the world.

The Society of Scientific Photography of Japan, established in 1926, and the Optical Science Section of the Society of Applied Physics of Japan, founded in 1952, have a total membership representing 90 per cent of the aforementioned scientists and research workers and regularly hold lectures, discussions and other meetings and publish periodicals. During 1954, over 150 research papers and reports on various aspects of photography were published.

In assessing the comparative levels of Japan's photographic science and technology, one can note that the quality of Japanese sensitive materials is the most highly advanced, followed by optical science. Cameras and accessories come third on the list.

The war and the confused situation of the immediate post-war years were major handicaps which hampered Japanese photographic research workers and cut them off from activities in foreign countries. However, various projects were undertaken. One group conducted a research into the reaction mechanism of chemical sensitizers and their adsorption to the silver halide surface by means of electrochemical methods.

Other groups sought to account theoretically for various anomalous effects of sensitizing. The research laboratory of one leading photographic manufacturer conducted studies to explain the mechanism of latent image formation and chemical sensitizing by experiments on the failure of the reciprocity law. Since 1941, research has been carried out on the ripening inhibitor contained in photographic gelatin. Natural and artificial ripening inhibitors for bromide emulsion, including known and unknown constituents, were tested and more than 130 inhibitors were synthesized. A part of these results was presented to the International Congress of Photography in 1953. Some excellent inhibitors were discovered by these researches—e.g., vitamin B_1 and penicillin G and their derivatives—and a convenient process was worked out for testing inhibiting power by the silver potential titration of the fog inhibitors.

An electron microscope cinematograph film dealing with the change of silver salt under exposure was successfully made by the same research laboratory referred to above. An ingenious process for manufacturing silver halide emulsion continuously by mixing and overflowing, followed by washing, was developed. Another firm introduced an improved process for manufacturing a new kind of printing paper in which polyvinyl alcohol is used as a vehicle instead of gelatin. This photographic paper has been placed on the market.

S.F.

Amateur Photography. About 3 million people own cameras in Japan, and of these about 60,000 are members of nearly 1,500 clubs, societies and other amateur photographic organizations established throughout the country. Of these organizations, there are eighty-eight amateur photographic clubs which have over one hundred members each, and twelve which have over 1,000 members each. The largest society is the All-Japan Association of Photographic Societies which has a membership of about 10,000 and is sponsored by the newspaper *Asahi Shimbun*. This organization was established in 1926, and among its annual activities are the International Photographic Salon and the All-Japan Photographic Salon.

Photographic contests are held regularly and are extremely popular. Among the outstanding ones is the Fuji Photo Contest sponsored by the Fuji Film Company, and in 1955 this had nearly 114,000 entries. In Tokyo there is an average of seven photographic exhibitions every month.

There are nine photographic magazines, of which the *Asahi Camera*, with a circulation of 180,000, is the largest. The *Asahi Camera*, *Camera Mainichi*, and *Sankei Camera* are published by newspaper companies. In addition, there are the *Nippon Camera*, *ARS Camera*, and other widely circulated photographic magazines. *ARS Camera*, which was first published in 1921, is the oldest amateur photographic magazine in Japan. There are several photographic annuals, such as the *Asahi Camera Annual*, *ARS Photographic Annual* and others. Lectures and books are also widely published.

Pictorial Photography. The carbon process was introduced into Japan about 1877 following research and experiments by Matsusaburo Yokoyama, but it was not widely adopted. However, after the introduction of gum prints and through exhibitions of foreign photography, from about 1894 Japanese photographers began to take an increased interest in pictorial photography.

With the establishment of the Tokyo Shashin Kenkukai and the Nihon Shashinkai (Photographic Society) in 1907, the trend toward pictorial photography became more marked. In 1915 a photographic course was included in the curriculum of the Tokyo Fine Arts School. In 1921 the magazine *Photographic Arts* was published.

Until about 1925 the various photographic trends apparent in English photographic periodicals and annuals exerted considerable influence in Japan. This phase produced such pictorial photographers as Shinzo Fukuhara.

The German trend of pictorial representation influenced Japanese photography from about

1930, but only for a short time; otherwise the tradition remained unchanged. Following the Pacific War, the influence of American journalistic photography with its emphasis on realism and humanism of the social scene became a major trend in the creative art and there was an increase of interest in workers like Ihee Kimura and Ken Domon, who are representative of the pictorial photographers of this period.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

The International Photographic Salon is the major photographic exhibition in Japan and is displayed in Tokyo and other cities; the 15th was held in 1955. Other important annual photographic exhibitions are the Japan Photographic Salon, and the Japan Photographic Art Exhibitions. In addition, a large number of photographic collections are printed and published each year. S.K.

Industry. The photographic industry in Japan—established mainly in the Tokyo area—has shown impressive expansion in output over the last five years, although the number of producers has remained relatively steady. In 1963 there were about fifty companies engaged in the production of photographic equipment and materials, many of which are also manufacturers of non-photographic goods, together providing employment for approximately 25,000 people.

By far the larger part of the industry has traditionally been occupied with the production of equipment and parts. Some thirty-five companies are mainly concerned with cameras, a further four are fully integrated manufacturers of lenses, whilst the remainder, apart from those which compose the sensitized goods sector (the two most important of which also manufacture cameras), are firms undertaking the production of accessories and parts.

There are six leading equipment manufacturers, which together account for about 50 per cent of the industry's total camera production, and an indication of their size may be gained from the number of their employees in 1963, which were as follows: Asahi Optical (1,300), Canon Camera (3,600), Minolta (1,800), Nippon Kogaku (2,200), Olympus Optical (600), and Yashica (2,600). Among these, during 1963 the Canon Camera Company produced over 450,000 still cameras and about 50,000 interchangeable lenses, whilst Yashica's output of still cameras was in the region of 700,000 units in addition to 150,000 cine cameras. Olympus Optical, who account for about 80 per cent of the industry's total production of "half-frame" 35 mm. still cameras, produced about 750,000 units.

The sensitized goods section of the industry has not been so highly developed and, although manufacturing all types of material, lags considerably behind that of other countries in the West, particularly in the field of colour film. Estimated total employment in this sector of the industry during 1963 was between 5,000 and 10,000 persons.

The leading manufacturer is the Fuji Photo Film Company, employing 5,900 persons in 1963, which produces still and cine film, X-ray film, sensitized paper, photographic chemicals and optical glass, and has in recent years begun the production of cameras and projection equipment. This company supplies about three-quarters of the domestic market for all types of film and approximately one-third of that for sensitized paper.

The other major producer of sensitized goods is the Konishiroku Photo Company, which has 3,600 employees and manufactures all types of film and plates and sensitized paper, in addition to cameras. There are two other main companies engaged in the manufacture of photographic paper, one of which also produces film, in addition to a small number of firms active in the photocopying field.

The industry has always been dependent to a large extent upon exports. Its development has been facilitated by the unrestricted entry of photographic goods allowed by the United States, which takes about one-third in value of total Japanese photographic exports, and more recently by the relaxation of tariff and quota barriers against Japanese equipment by several European countries. Government assistance in the form of company taxation relief and loans at low interest rates granted to export industries has also aided expansion.

There are three trade associations serving the photographic industry, the most important of which is the Japan Camera Industry Association. This is financed by its forty-five members, who account for about 90 per cent of the producers of cameras, lenses and accessories, and in addition to the usual functions of such bodies provides services in connection with design, research, and sales promotion work. A second organization, the Japan Camera Inspection Institute, has the function of inspecting and maintaining standards of quality in equipment destined for export markets.

Production. The value of Japanese production of photographic goods has more than doubled over the five years from 1959 to reach a total of $291·5 million in 1963.

The larger part of output is composed of equipment, totalling $199·1 million in the latter year, among which the most important items are still and cine cameras. An impressive rise in both quantity and value of these has taken place.

The type of still camera manufactured has changed since 1959 to emphasize the leading place held by 35 mm. and latterly the smaller format models, which together now compose the bulk of output, whilst the twin-lens reflex type has declined and the production of folding models has almost ceased.

The majority of cine cameras are 8 mm. models, and the large proportion of output taken by export markets is shown by the figures for 1963 when about three-quarters of total produc-

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

tion in both quantity and value.

Among other items of importance are lenses, and still and cine projectors, the output of the latter having been relatively low up to the present but is now undergoing expansion.

Sensitized goods, although accounting for less than one third of the total photographic production value in 1963, have shown considerable growth over the past five years.

Output of the largest single item, sensitized paper, has doubled in both quantity and value since 1959 to reach 37·6 million square metres worth $28·6 million in 1963, nearly all of which is due to black-and-white material. X-ray film has also shown expansion during the period to 3·6 million square metres with a value of $16·8 million in the latter year.

Production of still film and plates has expanded by about two-thirds in total over the past five years to reach 5·8 million square metres worth $33·6 million in 1963, almost all of which is composed of black-and-white material. In contrast, output of cine film has recorded only a small amount of growth, reaching 4·4 million square metres with a value of $13·4 million during 1963. The larger part of this is also accounted for by black-and-white stock, although the production of colour material is gradually increasing.

Imports. Imports of photographic equipment and materials by Japan are comparatively small in relation to the volume of goods exported. This is to a large extent the result of tariff and quota restrictions, coupled in the case of equipment with the expansion of the domestic industry in recent years, although during 1964 such restrictions are being released somewhat. Nevertheless, the total value of imported products has rather more than doubled in the five years since 1959 to reach $16·8 million in 1963.

Less than one-third of the total is attributable to apparatus, among which the largest single item is cine cameras. Imports of these totalled 2,150 units worth $470,000 in 1963, of which 16 mm. gauge models comprised 1,100 cameras valued at $445,000. The principal sources of the latter are the U.S.A., with 600 units worth $315,000 and Switzerland with 400 cameras valued at $47,000.

Still cameras represent the remaining product of importance, totalling 2,200 units with a value of $337,000 in 1963, the leading supplier of which is West Germany (600 cameras with a value of $88,000).

Sensitized materials comprise the larger part of imports and provided the bulk of their growth since 1959. Within the total value of $11·7 million in 1963, the largest product is cine film, worth $5·1 million. Among this product the major items are 35 mm. colour negative and positive stock (12·1 million metres worth $2·0 million), and 16 mm. black-and-white negative and positive material (27·3 million metres with a value of $1·4 million). The principal supplier of both types of film is the U.S.A., which accounted for 9·9 million metres valued at $1·7 million of the 35 mm. gauge stock, and 25·6 million metres worth $1·3 million of 16 mm. stock.

The other item of importance which has recorded considerable growth is roll film and plates, together totalling $4·4 million in 1963. The largest single products within the total are 35 mm. negative and reversal type film, reaching a total of 7,000 square metres with a value of $170,000, of which the U.S.A. supplied 3,500 square metres worth $95,000 and West Germany 3,000 square metres worth $66,000.

Exports. The value of photographic exports has recorded a substantial increase during the past five years, almost trebling since 1959 to reach a total of $91·5 million in 1963.

In keeping with the pattern of production, by far the greater part of exports is attributable to equipment which now accounts for 94 per cent of the total value, at $86·2 million. Still cameras are the leading product, exports of which reached 1·3 million units with a value of $36·0 million in 1963, and the accompanying table shows that the majority are 35 mm. models. The largest single market is the United States, taking 370,300 cameras worth $10·8 million during the year, with West Germany in second place (126,000 units valued at $2·9 million) and the United Kingdom third with 58,900 cameras worth $1·4 million.

The other major item which has shown an impressive rate of expansion in the period is cine cameras, exports of which attained 620,500 units with a value of $26·2 million in 1963. Nearly all of these are 8 mm. models (618,000 units worth $21·6 million), the principal purchasers being the U.S.A. with 300,700 cameras valued at $8·9 million, and West Germany with 50,100 cameras with a value of $2·1 million.

Among other products exported, photographic lenses hold an important place with 465,700 units worth $6·4 million in 1963, of which the United States received 231,000 lenses valued at 2·2 million.

Exports of cine projectors have also risen and almost quadrupled over the period, reaching 86,800 units with a value of $5·0 million during 1963. Of these, 8 mm. models accounted for 84,800 projectors worth $2·6 million, the principal markets being the United Kingdom (19,300 projectors worth $518,000) and West Germany (16,300 units valued at $476,000).

Still projector exports, although comparatively small, have risen since 1959 to reach a total of 131,000 units worth $1·3 million in 1963. Large purchasers of these are the United States, receiving 11,200 projectors worth $96,000, and the United Kingdom with 9,000 units valued at $81,000 during the year.

Exports of sensitized materials have expanded considerably over the past five years, although representing only a small part of total photographic goods, to reach $5·3 million in 1963.

The major product is sensitized paper,

totalling 7·1 million square metres with a value of £1·9 million, the larger part of which is composed of photocopy material. Principal markets for all types of paper in 1963 were the U.S.A. (3·2 million square metres worth $907,000), Formosa (0·5 million square metres valued at $280,000), and Sweden (0·5 million square metres worth $90,000).

Roll film and plates together account for the major part of the remaining materials exported, with 650,000 square metres worth $1·4 million in 1963. The largest item within the total is black-and-white roll film (493,000 square metres valued at $1·0 million), of which the leading purchasers are Brazil, taking 64,000 square metres valued at $196,000, and Hong Kong with 41,000 square metres worth $137,000.

Among other sensitized materials exported, cine films reached 17·4 million metres with a value of $862,000, of which 35 mm. black-and-white stock accounted for 10·2 million metres worth $426,000, the principal market being China with 4·4 million metres worth $151,000 in 1963.

JENA GLASS. Name for the optical glasses made in the Thuringian town of Jena.

As photography developed during the last century, it started the search for glasses with a much lower dispersion in relation to refractive index than had previously been required for optical work.

Glasses of this specification were first produced by Otto Schott and Ernst Abbe, working together. They joined forces in 1886 with Carl Zeiss and with the backing of the Prussian government started the large scale manufacture of the new optical glasses at Jena.

In a short time they gained almost a monopoly of the optical glass trade. The Jena factories continued to enjoy this monopoly until World War I. Since that time the optical glass industry developed in Great Britain has ended the exclusive supremacy of the Jena factories in that field.

JENKINS, C. FRANCIS, 1867–1934. American pioneer of cinematography. Founder and first President (1916) of the Society of Motion Picture Engineers. Designed in 1893–94 the Phantascope projector and camera with continuous movement and optical compensation. Prolific inventor holding more than 300 patents; in later years active in the field of radio and television. Autobiography: *The Boyhood of an Inventor* (1931).

JEWELLERY. Photographs of jewellery fall into two distinct categories; real jewellery and imitation, or costume, jewellery. Imitation jewellery is photographed for pictorial or catalogue purposes only, so it is easier to deal with, presents no special technical difficulties and can be handled by the ordinary studio.

Photographing real jewellery, because of its extreme value, is highly specialized work. There are many uses for such photographs, but it is a fairly limited market for photographers. First, because jewellery of this expensive class is also frail, jewellers are not very keen to let it be taken away from their premises. Most of the really important jewellers, in fact, have a photographic department on the premises run by their own photographic staff. Some set aside a room for the use of an outside photographer who may keep his own apparatus set up in position for use at any time.

A knowledge of gemmology and the crystallography and structure of precious stones is a great advantage for the photographer.

Jewellery in this category is photographed for many purposes apart from the pictorial and advertising interest. In one large firm all jewels that are regarded as important new creations are photographed so that the pictures may be interchanged between the various branches all over the world, so that designs and trends may be maintained at a high standard. Albums of these photographs are kept in the showrooms to assist clients in choosing designs around which their old and out-of-date jewellery can be remodelled. The photograph of the original jewel before remodelling can be of great assistance to the designer when making up the new design. Photographs are taken of these original jewels to keep a record of the stones before they are unmounted in case of any dispute afterwards.

Important jewellers hold photographic records of all pieces of jewellery made by them to hand to the police in the event of loss or burglary.

Photographs are also taken of large and specimen stones on offer in the London or

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

other markets. These are then sent to overseas branches for the consideration of likely purchasers as it is not advisable to keep sending stones backwards and forwards unless something definite is demanded. An X-ray photograph is sometimes taken of a pearl where there is a doubt about its being cultured. The pattern on the film caused by the deflection of the rays shows at once whether it is genuine or not. Photomicrographs taken of faults and inclusions enable a stone to be identified. Stones have actually been identified in a court of law by means of such a photograph taken years previously. A gem is often identified solely by photographs, and photography does provide a useful supplement to the normal records kept by the jeweller of each important stone.

Photographs are taken from a number of angles, including plan, from behind, and side views. These photographs are printed the same size and attached to the record. Enlargements may be made to indicate precisely the position of flaws and surface imperfections, and in some cases photomicrographs are made of superficial irregularities with the stone immersed in oil. The oil, which is highly refractive, creates an intense black line around the edge of the stone, clearly outlining the shape of the indentation.

Another photographic means of identifying stones is to record the pattern produced on a sensitive emulsion when a narrow pencil of light falls on the stone from a given angle. An extension of this method is to record the pattern of fluorescence produced by the diamonds in a piece of jewellery exposed to filtered ultraviolet light.

Diamonds are sometimes coloured artificially by exposing them to the radiations of radium. Where this has been done, it can be detected by putting the diamond in contact with a photographic plate in the dark for a period of several hours—if the stone has been radium treated, an image shows on the plate. X-ray records are also used to identify the details of the mount in which the gems are set.

Jewellery designers make considerable use of photography for enlarging or reducing a design, thereby saving themselves hours of work.

Equipment. Jewellery is usually photographed same size—as it loses a certain amount of definition and brilliance if enlarged. The best camera for this work is a 8 × 10 ins. process camera on rails mounted on trestles. A vertical easel covered with thick lino is used for pinning up jewels for photographing because they are displayed to better advantage hanging than lying flat.

An 18 ins. process lens is used as it is essential to have a long focus lens to keep the camera well away from the jewels and so allow sufficient space between lens and easel for manœuvring the lights. A vertical set-up on the principle of a copying camera is also useful for jewels that have to be laid down flat.

For general and perspective work, a whole plate stand camera with colour-corrected anastigmat lens is used. If it should be necessary to reduce the size of a jewel in taking the photograph, the amount of reduction is kept to the absolute minimum.

Lighting. The most suitable type of illumination is given by a floodlight with a general diffusing type of reflector, fitted with a 1500 watt tungsten light. A pointed or concentrated light certainly does not give as good results.

When lighting jewellery, the main source must always be supplemented with reflectors to fill in dark hollows in the stones which would otherwise debase their apparent quality. Small movable white reflectors on stands, adjustable white roller blinds on two sides opposite the light and a large white card reflector around the lens are used to highlight the reflecting surfaces of the jewels.

The main light source shines at an angle of 45° on to the subject.

Materials. Most coloured precious stones, such as emeralds, rubies and sapphires, reproduce darker on orthochromatic emulsions; and stones are usually more valuable when the colour is deeper. For this reason ortho films are often preferred. But a panchromatic emulsion is used when a fault or inclusion is to be photographed.

Colour transparencies of jewellery are made on reversal colour film, using tungsten light and a correction filter. It is usual for salesmen to take out 2 × 2 ins. colour slides and a viewer to avoid carrying too much jewellery.

Background. The detail and beauty in stones is always more apparent when the background is kept simple. A fine-grained linen paper—of a suitable shade—is generally sufficient.

To avoid shadows which may obscure the detail of the delicate mountings, the piece may be fixed to a sheet of glass with cellulose cement. The glass is then supported a few inches away from the background.

The finished print is made on a brilliant black-and-white bromide paper and is always glazed to add sparkle. A.C.K.

JOHNSTON, JOHN DUDLEY, 1868–1955. English amateur photographer. Honorary Secretary, Curator and Editor of the Royal Photographic Society. A founder of the Photographic Alliance of Great Britain and a well-known lecturer, exhibitor and exhibition judge. President of the R.P.S. 1923–25 and 1929–31; received their Progress Medal in 1951.

JOIN-UP. Panoramic and wide angle views can be made by joining several pictures, each of which contains part of the scene. The prints used must overlap each other to allow for trimming to exact line of joining. For minimum distortion, strict rules must be observed when shooting.

See also: *Panorama.*

JOLY, JOHN, 1857–1933. Dublin professor. Was a pioneer in screen-plate colour photography. His linear screen-plate process (1893) was the forerunner of many other additive colour processes, such as the Thames, the Paget, and the Dufay plate and film, to mention but the more important.

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

JONES, HENRY CHAPMAN, 1855(?)–1932. English chemist and photographer. President of the Royal Photographic Society, 1912–14. Instructor in, and writer of books on, photography. In 1901 introduced a sensitometer, under the name of the Chapman Jones Plate Tester, that was widely used by photographic manufacturers in England. It replaced the Warnerke sensitometer.

JONES, LOYD ANCILE, 1884–1954. American physicist and electrical engineer. Joined the Research Laboratories of the Eastman Kodak Company on their establishment in 1912 and worked there (later as Head of the Physics Division) until his retirement a fortnight before his death. Specialized in sensitometry and the measurement of the properties of photographic emulsions. Received in 1948 the Progress Medal of the Royal Photographic Society "for his great and outstanding contributions to photographic science and practice, notably in the field of sensitometry".

JOULE. Unit of energy, equal to 10,000,000 ergs, or 1 watt-second. It is named after J. P. Joule (1818–89) who first formulated a mechanical equivalent of heat energy. In photography joules are used to measure the energy discharged in an electronic flash tube. In terms of light output of an electronic flash, 1 joule is approximately equivalent to 40 lumen-seconds.

See also: *Light units.*

JUDGES FOR EXHIBITIONS. Most photographic exhibitions are judged by qualified persons having no direct interest in the organization holding the exhibition.

In Britain, the various area Federations of amateur photographic societies maintain panels of judges; these are listed collectively in a publication of the central body, the Photographic Alliance. All of these judges are available to affiliated societies. In some cases, specialists are listed for exhibitions devoted to particular subjects (e.g., nature photography).

In other cases, it is common for well-known photographers, picture magazine editors, and artists to be invited to judge photographic exhibitions. Provided that the exhibition is of a reasonable standard and size, a courteous letter will frequently produce agreement to judge an exhibition; but adequate notice must always be given.

Invited judges sometimes prefer to have the exhibition entries sent to their home or office for selection; others may visit the organizers' headquarters for the purpose. Always, however, selection is carried out at least a few days before the exhibition is due to open so that the catalogue can be prepared and printed. Frequently the judge will also attend either the opening of the exhibition or a meeting at which a commentary on the prints is given and any lantern slide entries are projected.

At all times, the decisions of the judge must be sincerely respected.

JUDGING EXHIBITION ENTRIES. Every year thousands of photographs are submitted to pictorial photographic exhibitions by entrants who hope that their pictures will be considered good enough to be accepted for hanging. The experts chosen by the organizers to perform the task of selection are called judges (and sometimes also selectors, jurors, or critics). Their function is to consider the pictures submitted and select those which in their opinion possess the highest merits.

The selection of a picture for hanging is not decided by the whim of the judge; there are a number of systems for arriving at a fair assessment of the merits of a print. There is usually a simple explanation for any apparent anomalies. For example, an entrant may have his picture accepted by one well-known exhibition and yet rejected by another. In such circumstances he may quite well feel that the judges cannot be right in both cases and that he has a legitimate grievance. But he may not be competing against prints of the same standard on both occasions, and the best at one exhibition may be the second best at the other.

The number of prints accepted varies from one exhibition to another. Any pictorial exhibition approved by the Royal Photographic Society of Great Britain in this country, and by the Photographic Society of America in America displays all accepted prints so that they can be properly seen by the general public. But the space available varies from large wall spaces in a first-class art gallery to comparatively few screens in a small local hall. The organizers of the exhibition at their preliminary meeting have to weigh the space available for their final display against the total entry they are likely to receive and the proportion of this entry it is advisable or possible to hang.

The average open international exhibition ("open" in this case meaning that the exhibition is not confined to members of a particular society or club) receives on the average from 500 to 1,000 entries from all over the world. Bigger exhibitions, like the Royal Photographic Society's Annual Pictorial Exhibition and that of the London Salon of Photography, may receive anything from four to six thousand prints. As in neither of these cases will more than two or three hundred

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

prints be hung in the gallery space available, the percentage of entries displayed is naturally small. Acceptance at such exhibitions is therefore more highly prized. The average provincial exhibition usually hangs one in three or one in four of the prints submitted, unless, as occasionally happens, the standard is unusually low. So it follows that a print rejected from the major salons may quite well be accepted in a less well-patronized exhibition.

Sometimes there is only one judge, but generally a panel of judges makes the selection. A panel consists of an uneven number; say three, five, or occasionally seven, so that in a case of dispute they can return a majority verdict.

A good judge must be an experienced critic, able to make up his mind quickly. He should be able to see at a glance whether a photograph shows evidence of original thought or is merely a slavish copy of somebody else's previous exhibition success. And he should know what constitutes a generally accepted standard of good pictorial photography. The judge must also be free from prejudices against certain types of subject; he should be open to new ideas and not hide-bound by tradition. Even so, in the end much depends upon his personal taste in pictures.

It is not always appreciated that judges give their time freely in return for nothing more than their out-of-pocket expenses, and there are not many experienced judges who have enough leisure to travel from one part of the country to another on this arduous work. The soundness of a judge can be proved only by the resulting exhibition and while it is not possible for the judge to please everybody, he soon loses his reputation if the majority of experienced photographers consistently disagrees with his selection.

Amateur photographic organizations in some countries maintain lists of judges prepared to give their services free (excepting expenses).

The A, B and C Method. There are various methods of judging, but the most popular is what is known as the A, B and C method. Under this system there is open discussion between the members of the panel. The pictures are put up one by one in front of the panel and each member in turn classifies the picture as A, B or C. A signifies that they consider it well up to the standard required, B that it is not quite equal to the A standard, but is worthy of further consideration and discussion, and C that it is below standard. If with a panel of three there is one A and two B's, the print will go into the B category and come up for further consideration, whereas if there are two A's and one B, the print will be classified as A. C prints are not generally viewed a second time.

When the first round has been completed, the total number of A's and B's is counted and if for example the organizers have a thousand entries and decide to hang two hundred and fifty pictures and there are only one hundred A's, then the B's are gone through again and the best of these selected. If the total number of A's and B's does not reach the desired number on this round, the organizers will have to put up with a smaller number, and this often happens. For example, the gallery accommodation may be sufficient for two hundred and fifty pictures, but the total A's and B's may not add up to more than two hundred. In such a case only two hundred pictures will be hung.

Marking Method. Some judges prefer to allot marks, say from one to ten, to each print, according to their opinion of its merits. The total number of prints selected for the exhibition is then made up by going down the list of each category and taking all the tens, then all the nines, and so on down until the total number desired is reached. The objection to such a system of judging is that it is impossible to attach numbers to abstract qualities with any degree of accuracy.

Push Button Method. In the third system, known generally as Push Button judging, each judge has an electrical device consisting of three push buttons, or a three-position switch for the A, B and C categories. The voting is done secretly and one judge does not know which way the others are voting. Those who advocate this method claim that it prevents any one judge from dominating the others, but those who oppose it say that it is fairer to the entrant to have a free discussion amongst the judges on the merits of the picture and that in any case a judge who allows himself to be dominated by others will not maintain his reputation very long.

Points Method. Another idea that has been tried without much success has been to provide each picture with a sheet listing a large number of qualities to which the judges allot points. The various qualities may reach as many as twenty and include among other things, technique, presentation, originality of ideas, composition, and emotional impact. With twenty such categories and a maximum of ten marks in each category, the ideal or perfect print would have a possible two hundred marks. The difficulty is that no one can dissociate the various qualities that go to make a good picture, or say that any one quality is more important than another. Finally, even if the judges were skilful enough to consider each print in this way, to do it conscientiously would take up too much time.

Popular Vote. Occasionally attempts have been made to submit the judgement to popular vote, leaving the visitors to decide which prints are the best. The usual procedure is to give each visitor a form in which, for example, he is asked to place say the ten best prints in order of merit. Unfortunately in this as in

many other branches of life the mere counting of heads does not produce wisdom. Certain types of pictures are "sure-fire winners" in popular voting. Young and pretty looking kittens and puppies; children with their hands in jam-pots and with jam-covered faces; cats in baskets; kittens in boots; very small children with a highly sentimental or somewhat sugary appeal.

Then there are certain conventions that the general public expects the photographer to observe. For example, the sharper the picture, the better; a broad treatment of tones, or any picture which faithfully reproduces the soft mistiness of evening light or early morning fog will be peered at closely and dismissed as "not sharp".

No method of judging prints is perfect, but it is generally agreed that the A, B and C system is the best available and it has now been adopted for most of the exhibitions in this country and abroad. P.W.H.

K

KALLITYPE. Obsolete printing process introduced by Dr. W. J. Nichol in 1899, based on Herschel's argentotype. Similar in appearance to platinotype but forming an image in metallic silver instead of platinum.

See also: *Obsolete printing processes.*

KALVAR PROCESS. Proprietary name of a low-speed heat-developable light-scattering photographic system. The image is produced by the decomposition of diazo compounds in a plastic layer, liberating nitrogen. On heating, the nitrogen forms minute bubbles in the plastic layer, producing a vesicular light-scattering image.

See also: *Diazo processes.*

KÄSEBIER, GERTRUDE, 1852–1934. American pictorial photographer. Founder member of the Photo-Secession, 1902.

KATAPOSITIVE. Positive printed on an opaque base to be viewed by reflected light as opposed to a diapositive which is printed on a transparent base to be viewed by transmitted light. The term is rarely used to-day.

KATUSHEV, JAKOV MATVEEVICH, 1885–1958. Russian specialist in scientific photography. Consultant to the Central Laboratory of Cinematographic Chemistry 1928–33 and Professor of Photographic Chemistry in the Moscow Polygraphic Institute 1937–46. Received Order of Lenin for scientific research and educational activities.

KEEPING QUALITIES OF MATERIALS. The length of time sensitive materials stay fresh depends on the storage conditions, the chemical properties of the support and the dyes used for colour sensitizing.

Storage Conditions. Certain conditions make negative materials deteriorate rapidly: moisture or high atmospheric humidity, high temperatures and the presence in the atmosphere of fumes and gases (e.g., sodium sulphide, or fumes from burning fires) which react with the silver halide in the emulsion.

Sensitized materials keep best in a cool, dry place, well away from smoke, fumes and volatile substances. Special precautions are required in tropical and other extreme climatic conditions. The effects of unsuitable storage conditions on sensitized emulsions are loss of speed, sometimes with increase of contrast, increased fog level and mottling, streaks, and patches caused by the uneven action of damp, fumes or high temperature.

Chemical Properties of the Support. Most emulsions lose speed when kept for any length of time. Plate materials suffer least; under normal conditions they may remain usable for many years. With films the plasticisers added to the base may affect the emulsion characteristics in time. This risk is virtually absent with modern polyester and similar supports. In the days of cellulose nitrate films the products of the gradual decomposition of cellulose nitrate also interfered with the emulsion and the latent image during storage. The paper base of printing papers has no adverse effect on keeping qualities, though these materials, too, lose speed and change in contrast on storage.

Sensitizing Dyes. In orthochromatic and panchromatic negative materials the sensitizing dyes tend to decompose very slowly. This lowers the speed and alters the colour sensitivity. In colour films of the multilayer type the decomposition of the sensitizing dyes may upset the colour balance.

Ordinary roll films will keep their speed and general characteristics up to about two years from the date of manufacture, so long as they are properly stored. An expiry date is usually stamped on the film carton.

Expiry Date. Film materials are generally still usable even after the expiry date, although they will not be as fast as when new. Special precautions—e.g., using a developer improver—should, however, be taken when developing

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

stale materials in order to keep down fog. Colour films are less likely to be usable if good colour rendering is required as the emulsion characteristics in the individual layers are liable to change at different rates. This tends to affect the colour balance during storage.

The dyes used for sensitizing negative emulsions to the more extreme infra-red radiations are very unstable and in consequence the materials are usable only up to a few weeks from the date of sensitizing. Manufacturers often make such emulsions to special order only. Even then the films or plates may have to be stored with solid carbon dioxide at temperatures of around −80° C. to slow down the rate of deterioration. Low temperature storage is also important in order to eliminate fogging from heat radiations which may affect infra-red materials of long-range sensitivity.

Because plates and printing papers keep better than films, expiry dates are not usually given for them. Papers especially keep well for several years if properly stored, and the loss of speed rarely matters. Here, too, special precautions—e.g., use of developer improvers—are advisable when processing old material.

Some scientific materials have to be hypersensitized before use to give them the highest possible speed. Such hypersensitized materials will only retain their extra speed for a few days. After that time they lose their speed again, but increase in fog density.

Exposed Materials. Long storage of materials after exposure and before development may partially destroy the latent image and thus reduce the effective speed of the emulsion. This applies particularly to high-speed emulsions. Exposed materials should therefore be developed as soon as possible. This is specially important with colour materials where a delay of development of more than two months may noticeably alter the results. L.A.M.

KEIGHLEY, ALEXANDER, 1861–1947. English amateur pictorial photographer. Exhibited at the Photographic Society (later Royal) in 1889 and afterwards in many European and American cities. Many of his most famous pictures were taken with a box camera, disguised in brown paper. Started print-making *c.* 1883 with albumen paper and later used Platinotype and carbon. Often made exhibition pictures from enlarged 16 × 20 in. negatives printed by contact in daylight. Biography: *Alexander Keighley 1883–1947* (Royal Photographic Society, London, 1947).

KEITH, THOMAS, 1827–95. Scottish gynaecologist and surgeon in Edinburgh and amateur photographer 1853–56. Dr. Keith made splendid architectural and landscape photographs of Edinburgh and the surrounding country by the waxed paper process.

KELLER-DORIAN, ALBERT, 18??–1924. French photo-engraver and manufacturer of textile embossing rollers. Pioneer of an additive three-colour cinematography process using lenticular films (with minute embossed lenses on one side of the film support, and with a panchromatic emulsion on the other). Through a three-colour filter separation of colours, images are formed in the emulsion, which are reversed in development; when projected with a similar filter they produce a picture in natural colours (1908). The Keller-Dorian process was improved by Berthon and became known as the K.D.B. process, the rights of which were acquired by the Eastman Kodak Company. They improved and marketed it in 1928 under the name Kodacolor. Another version was the Siemens-Berthon process and the Agfa amateur colour film.

KELVIN DEGREES. Units on the absolute scale of temperature, numerically equal to degrees Centigrade plus 273. Named after W. T. Kelvin (1824–1907) and used for measuring colour temperatures of light sources.

See also: *Colour temperature.*

KENNETT, RICHARD, 1817–96. English amateur photographer. Produced and patented stable silver bromide gelatin pellicles in 1873. These could be kept and, when swelled and melted in water, used to coat glass plates, thus replacing collodion. In 1874 he produced dry silver bromide gelatin plates which were manufactured, 1876.

KEPLER, JOHANNES, 1571–1630. German astronomer. Discoverer of the inverse square law relating the intensity of light with the distance it travels from the source. Founder of modern optics by his book, *Dioptrice*, published in Augsburg, 1611. Enunciated the laws of planetary motion. For topographical sketches used, before 1620, a tent camera obscura with a revolvable lens tube projecting through the top, which projected images on to the paper. Biography by D. Brewster (8th ed. 1874).

KERR CELL. "Shutter" used in high speed photography consisting of a glass tank filled with a fluid which, in conjunction with a pair of polarizing screens, will allow light to pass through it when a high voltage is applied. This permits exposure times of less than 1/1,000,000 second.

KEY. A photograph can be an acceptable picture without including the whole of the tone scale from black to white that is usually present in photographs. The image may consist of only a few shades of grey selected from any part of the tone scale.

If tones are taken from the lower end of the scale the picture will be made up of black

and a few shades of dark grey with only small areas of highlights. The general impression will be one of sombre colour. A picture of this type is said to be in a low key.

If the image is formed by a few pale grey tints and white paper, it will convey an impression of lightness and delicacy. Such a picture is said to be in a high key.

The photographer may set out deliberately to restrict the number of tones in the final picture. He may wish to produce either a high or a low key picture to suit the special character of the subject.

A true high or low key picture is produced by restricting the tones of the original image—i.e., by manipulation or selection of the lighting. A portrait of a fair-haired subject wearing light-toned clothing and photographed against a white background by soft lighting from the front will produce a high key picture without any departure from normal exposing and processing technique. The delicate atmosphere of such a picture cannot be imitated by taking an ordinary photograph and falsifying its tones in development or exposure or by any kind of aftertreatment of the print.

In the same way, a true low key picture can be produced only as a result of low key lighting; it is not a print that has been deliberately over-exposed or over-developed.

See also: *High key; Low key.*

K-FILTERS. Colour filters made by dyeing gelatin with the dye Filter Yellow K. Once necessary with early pan and ortho materials.

KILO. Prefix signifying a thousand in the metric system—e.g., kilogram, kilometre. Seldom needed in photography.

See also: *Weights and measures.*

KILOWATT. One thousand watts. Sometimes a more convenient practical unit of electrical power than the watt.

KILOWATT HOUR. Commercial unit of electricity consumption; the amount of power used in one hour by an apparatus rated at 1,000 watts or one kilowatt.

KINEMATOGRAPH. (Greek, kinema = movement.) More correct, but less common, term for cinematograph.

KIRCHER, ATHANASIUS, 1601–80. German mathematician and scholar. Gave descriptions of the camera obscura 1646, magic lanterns and other optical instruments 1671. Is often named (erroneously) as the inventor of the optical lantern.

KITES. Cameras suspended from kites have been used for taking aerial photographs of the ground. A series of exposures may be made automatically by a clockwork mechanism which transports the film and sets the shutter, or a single exposure may be made by setting a clockwork or wind-driven delay mechanism before the flight.

See also: *Balloons and kites.*

KLIČ, KAREL, 1841–1926. Czech painter and newspaper artist. Creator of modern photogravure; he combined the use of the half-tone screen, carbon tissue, aquatint grain and iron chloride etchants (1879). Also introduced rotogravure—the process of printing intaglio cross-line screen images from cylinders on high-speed rotary presses (1895). Biography *Karl Klietsch* by K. Albert (Vienna 1927).

KNIFING. Removal of opaque blemishes from a negative or print by scraping with a knife.

The action of knifing actually removes fine layers of emulsion until the density has been reduced by the required amount.

See also: *Retouching.*

KOBELL, FRANZ VON, 1803–75. German mineralogist, Professor at University of Munich. He and Steinheil were the first in Germany (1839), to make paper negatives by their own process, similar to Talbot's. Also made photomicrographs at an early date and invented the galvanographic (non-photographic) reproduction of paintings in 1840. Biography by A. Dreyer (Munich 1904).

KODACHROME. Pioneer subtractive process of colour photography worked out by L. D. Mannes and L. Godowsky and introduced by Kodak in 1935. It makes use of an integral tripack in which the emulsions contain no colour formers but are subjected to individual dye development.

See also: *Colour history.*

KODACOLOR. Originally an additive method of producing colour photographs with the aid of a lenticular screen embossed on the front of the film. It was first made available commercially in 1928 on 16 mm. cine film. The name is now applied to a negative-positive process for making subtractive colour prints.

See also: *Cine history; Colour photography history.*

KODAK. Trade name of Kodak Limited, coined by George Eastman, founder of the organization, in 1888 and first registered in Great Britain on May 3rd, 1888, then in the United States on September 4th, 1888, and subsequently in many other countries. It was first used in connexion with Eastman's original box-type camera. Eastman was determined to adopt a trade mark that could not be misspelled or mispronounced, in any language, or infringed or copied by anyone. He wanted a strong word that could be registered and that

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

CC-0. Agamnigam Digital Preservation Foundation, Chandigarh

everyone could remember and associate with the products of his manufacture. He based it on the letter K, which attracted him because it was "firm and unyielding" and easily pronounced, and by a process of association and elimination he arrived at the word Kodak.

See also: *Camera history.*

KODALK. Proprietary alkali of the sodium metaborate type used in developers.

Characteristics: White crystalline powder.

Solubility: Freely soluble in water at room temperature.

KÖNIG, ERNST, 1869–1924. German dyechemist. Producer of many sensitizers of which orthochrome, pinaverdol, pinachrome and others have played an immensely valuable part in ortho- and panchromatic photography (from 1904), and the di- and tri-carbocyanines (1923) have extended the sensitivity into the extreme red and near infra-red. Pure filter dyes were also produced by König and he also investigated the desensitizers discovered by Lüppo-Cramer. He invented pinachromy by leuco bases, and was author of a number of books on colour photography.

KOSTINSKY EFFECT. Phenomenon of development resulting in the shifting of the relative position of two image points situated very close to each other. The shift is the result of the change in the concentration of active—or exhausted—developer ingredients immediately between the points.

Where two heavily exposed point images are developing in a solution without agitation, they rapidly exhaust the developer in contact with them. When that happens, they depend for further increase in density on the fresh solution that diffuses from the emulsion around them. If the points are close together, the solution in between them becomes exhausted at a very early stage and development ceases where the points are closest.

On the outside of each point, however, the images can go on developing because a supply of fresh developer is constantly diffusing through the emulsion from unexposed areas to take the place of the exhausted solution.

The result of this selective action is that the nearer borders of each point stop developing while the outer borders continue, so the regions of maximum density move away from each other and the point images appear farther apart than they would have done if development had been even all over.

The opposite effect occurs when the negative image consists of clear spots on a dense ground. In this case, the solution lying immediately between the points becomes exhausted and fresh solution diffuses inwards from the clear spots. The supply is limited, however,

KOSTINSKY EFFECT. Developer between closely spaced heavy image points gets exhausted and under-develops areas closest to each other, so that image points appear to move apart. The opposite occurs with clear spots on a dark ground.

and the demands of the heavily exposed space between the points is great. So the adjacent borders of the image points cannot get enough fresh developer to satisfy their needs, and the margins remain clear instead of developing to a visible density. The demands for fresh solution at the outer edges of the spots are only about half as great, so the image develops at full strength right up to the edge. The net effect of all this is that the clear spots grow on their nearer borders and so appear closer.

Image movements of this type cause errors in certain scientific measurements based on photography and produce distortion of the sound record in cinematography. F.P.

See also: *Eberhard effect.*

KROMSKOP. Instrument (invented by F. E. Ives, 1892) for viewing monochrome colour separation transparencies through a system of mirrors and colour filters to produce a natural colour picture by additive synthesis. The mirrors were arranged so that the images of the separation transparencies were all combined in register. The transparencies were illuminated by a single source and the single or stereosopic colour image viewed through eyepiece lenses.

KRONE, HERMANN, 1827–1916. German landscape and portrait photographer, and professor of scientific photography at the Dresden Polytechnic (later Technical College). Investigated multiple solarization in 1851. Worked for a time with Taupenot's collodio-albumen process, and experimented with the Lippmann colour process.
